

Practical Verified Computation with Streaming Interactive Proofs

Graham Cormode*

Michael Mitzenmacher[†]

Justin Thaler[‡]

Abstract

When delegating computation to a service provider, as in the cloud computing paradigm, we seek some reassurance that the output is correct and complete. Yet recomputing the output as a check is inefficient and expensive, and it may not even be feasible to store all the data locally. We are therefore interested in what can be validated by a streaming (sublinear space) user, who cannot store the full input, or perform the full computation herself. Our aim in this work is to advance a recent line of work on “proof systems” in which the service provider *proves* the correctness of its output to a user. The goal is to minimize the time and space costs of both parties in generating and checking the proof. Only very recently have there been attempts to implement such proof systems, and thus far these have been quite limited in functionality.

Here, our approach is two-fold. First, we describe a carefully chosen instantiation of one of the most efficient general-purpose constructions for arbitrary computations (streaming or otherwise), due to Goldwasser, Kalai, and Rothblum [19]. This requires several new insights and enhancements to move the methodology from a theoretical result to a practical possibility. Our main contribution is in achieving a prover that runs in time $O(S(n) \log S(n))$, where $S(n)$ is the size of an arithmetic circuit computing the function of interest; this compares favorably to the $\text{poly}(S(n))$ runtime for the prover promised in [19]. Our experimental results demonstrate that a practical general-purpose protocol for verifiable computation may be significantly closer to reality than previously realized.

Second, we describe a set of techniques that achieve genuine scalability for protocols fine-tuned for specific important problems in streaming and database processing. Focusing in particular on *non-interactive* protocols for problems ranging from matrix-vector multiplication to bipartite perfect matching, we build on prior work [8, 15] to achieve a prover that runs in nearly linear-time, while obtaining optimal tradeoffs between communication cost and the user’s working memory. Existing techniques required (substantially) superlinear time for the prover. Finally, we develop improved *interactive* protocols for specific problems based on a linearization technique originally due to Shen [34]. We argue that even if general-purpose methods improve, fine-tuned protocols will remain valuable in real-world settings for key problems, and hence special attention to specific problems is warranted.

1 Introduction

One obvious impediment to larger-scale adoption of cloud computing solutions is the matter of trust. In this paper, we are specifically concerned with trust regarding the *integrity* of outsourced computation. If we store a large data set with a service provider, and ask them to perform a computation on that data set, how

can the provider convince us the computation was performed correctly? Even assuming a non-malicious service provider, errors due to faulty algorithm implementation, disk failures, or memory read errors are not uncommon, especially when operating on massive data.

A natural approach, which has received significant attention particularly within the theory community, is to require the service provider to provide a *proof* along with the answer to the query. Adopting the terminology of proof systems [2], we treat the user as a verifier $\mathcal{V}$, who wants to solve a problem with the help of the service provider who acts as a prover $\mathcal{P}$. After $\mathcal{P}$ returns the answer, the two parties conduct a conversation following an established protocol that satisfies the following property: an honest prover will always convince the verifier to accept its results, while any dishonest or mistaken prover will almost certainly be rejected by the verifier. This model has led to many interesting theoretical techniques in the extensive literature on *interactive proofs*. However, the bulk of the foundational work in this area assumed that the verifier can afford to spend polynomial time and resources in verifying a prover’s claim to have solved a hard problem (e.g. an NP-complete problem). In our setting, this is too much: rather, the prover should be efficient, ideally with effort close to linear in the input size, and the verifier should be lightweight, with effort that is *sublinear* in the size of the data.

To this end, we additionally focus on results where the verifier operates in a streaming model, taking a single pass over the input and using a small amount of space. This naturally fits the cloud setting, as the verifier can perform this streaming pass while uploading the data to the cloud. For example, consider a retailer who forwards each transaction incrementally as it occurs. We model the data as too large for the user to even store in memory, hence the need to use the cloud to store the data as it is collected. Later, the user may ask the cloud to perform some computation on the data. The cloud then acts as a prover, sending both an answer and a proof of integrity to the user, keeping in mind the user’s space restrictions.

We believe that such mechanisms are vital to expand the commercial viability of cloud computing services by allowing a trust-but-verify relationship between the user and the service provider. Indeed, even if every computation is not explicitly checked, the mere ability to check the computation could stimulate users to adopt cloud computing solutions. Hence, in this paper, we focus on the issue of the practicality of streaming verification protocols.

There are many relevant costs for such protocols. In the streaming setting, the main concern is the space used by the verifier and the amount of communication between $\mathcal{P}$ and $\mathcal{V}$. Other important costs include the space and time cost to the prover, the runtime of the verifier, and the total number of messages exchanged between the two parties. If any one of these costs is too high, the protocol may not be useful in real-world outsourcing scenarios.

In this work, we take a two-pronged approach. Ideally, we would like to have a general-purpose methodology that allows us to construct an efficient protocol for an arbitrary computation. We therefore examine the costs of one of the most efficient general-purpose protocols known in the literature on interactive proofs, due to Goldwasser, Kalai, and Rothblum [19]. We describe an efficient instantiation of this protocol, in which the prover is significantly faster than in prior work, and present several modifications which we needed to make our implementation scalable. We believe our success in implementing this protocol demonstrates that a fully practical method for reliable delegation of arbitrary computation is much closer to reality than previously realized.

Although encouraging, our general-purpose implementation is not yet practical for everyday use. Hence, our second line of attack is to improve upon the general construction via specialized protocols for a large subset of important problems. Here, we describe two techniques in particular that yield significantly more scalable protocols than previously known. First, we show how to use certain Fast Fourier Transforms to obtain highly scalable *non-interactive* protocols that are suitable for practice today; these protocols require

just one message from $\mathcal{P}$ to $\mathcal{V}$, and no communication in the reverse direction. Second, we describe how to use a ‘linearization’ method applied to polynomials to obtain improved *interactive* protocols for certain problems. All of our work is backed by empirical evaluation based on our implementations.

Depending on the technique and the problem in question, we see empirical results that vary in speed by five orders of magnitude in terms of the cost to the prover. Hence, we argue that even if general-purpose methods improve, fine-tuned protocols for key problems will remain valuable in real-world settings, especially as these protocols can be used as primitives in more general constructions. Therefore, special attention to specific problems is warranted. The other costs of providing proofs are acceptably low. For many problems our methods require at most a few megabytes of space and communication even when the input consists of terabytes of data, and some use much less; moreover, the time costs of $\mathcal{P}$ and $\mathcal{V}$ scale linearly or almost linearly with the size of the input. Most of our protocols require a polylogarithmic number of messages between $\mathcal{P}$ and $\mathcal{V}$, but a few are non-interactive, and send just one message.

To summarize, we view the contributions of this paper as:

- A carefully engineered general-purpose implementation of the circuit checking construction of [19], along with some extensions to this protocol. We believe our results show that a practical delegation protocol for arbitrary computations is significantly closer to reality than previously realized.
- The development of powerful and broadly applicable methods for obtaining practical specialized protocols for large classes of problems. We demonstrate empirically that these techniques easily scale to streams with billions of updates.

1.1 Previous Work

The concept of an interactive proof was introduced in a burst of activity around twenty years ago [3, 20, 25, 33, 34]. This culminated in a celebrated result of Shamir [33], which showed that the set of problems with efficient interactive proofs is exactly the set of problems that can be computed in polynomial space. However, these results were primarily seen as theoretical statements about computational complexity, and did not lead to implementations. More recently, motivated by real-world applications involving the delegation of computation, there has been considerable interest in proving that the cloud is operating correctly. For example, one line of work considers methods for proving that data is being *stored* without errors by an external source such as the cloud, e.g., [22].

In our setting, we model the verifier as capable of accessing the data only via a single, streaming pass. Under this constraint, there has been work in the database community on ensuring that simple functions based on grouping and counting are performed correctly; see [37] and the references therein. Other similar examples include work on verifying queries on a data stream with sliding windows using Merkle trees [24] and verifying continuous queries over streaming data [29].

Most relevant to us is work which verifies more complex and more general functions of the input. The notion of a streaming verifier, who must read first the input and then the proof under space constraints, was formalized by Chakrabarti *et al.* [8] and extended by the present authors in [15]. These works allowed the prover to send only a single message to the verifier, with no communication in the reverse direction. With similar motivations, Goldwasser *et al.* [19] give a powerful protocol that achieves a polynomial time prover and highly-efficient verifier for a large class of problems, although they do not explicitly present their protocols in a streaming setting. Subsequently, it has been noted that the information required by the verifier can be collected with a single initial streaming pass, and so for a large class of uniform computations, the verifier operates with only polylogarithmic space and time. Finally, Cormode *et al.* [17] introduce the notion of streaming interactive proofs, extending the model of [8] by allowing multiple rounds of interaction

between prover and verifier. They present exponentially cheaper protocols than those possible in the single-message model of [8, 15], for a variety of problems of central importance in database and stream processing.

A different line of work has used fully homomorphic encryption to ensure integrity, privacy, and reusability in delegated computation [18, 12, 11]. The work of Chung, Kalai, Liu, and Raz [11] is particularly related, as they focus on delegation of streaming computation. Their results are stronger than ours, in that they achieve reusable general-purpose protocols (even if $\mathcal{P}$ learns whether $\mathcal{V}$ accepts or rejects each proof), but their soundness guarantees rely on computational assumptions, and the substantial overhead due to the use of fully homomorphic encryption means that these protocols remain far from practical at this time.

Only very recently have there been sustained efforts to use techniques derived from the complexity and cryptography worlds to actually verify computations. Bhattacharyya implements certain PCP constructions and indicates they may be close to practical [4]. In parallel to this work, Setty *et al.* [31, 32] survey results on probabilistically checkable proofs (PCPs), and implement a construction originally due to Ishai *et al.* [21]. While their work represents a clear advance in the implementation of PCPs, our approach has several advantages over [31, 32]. For example, our protocols save space and time for the verifier even when outsourcing a single computation, while [31, 32] saves time for the verifier only when batching together several dozen computations at once and amortizing the verifier’s cost over the batch. Moreover, our protocols are unconditionally secure even against computationally unbounded adversaries, while the construction of Ishai *et al.* relies on cryptographic assumptions to obtain security guarantees. Another practically-motivated approach is due to Canetti *et al.* [7]. Their implementation delegates the computation to two *independent* provers, and “plays them off” against each other: if they disagree on the output, the protocol identifies where their executions diverge, and favors the one which follows the program correctly at the next step. This approach requires at least one of the provers to be honest for any security guarantee to hold.

1.2 Preliminaries

Definitions. We first formally define a valid protocol. Here we closely follow previous work, such as [17] and [8].

Definition 1.1 Consider a prover $\mathcal{P}$ and verifier $\mathcal{V}$ who both observe a stream $\mathcal{A}$ and wish to compute a function $f(\mathcal{A})$. After the stream is observed, $\mathcal{P}$ and $\mathcal{V}$ exchange a sequence of messages. Denote the output of $\mathcal{V}$ on input $\mathcal{A}$, given prover $\mathcal{P}$ and $\mathcal{V}$ ’s random bits $\mathcal{R}$, by $\text{out}(\mathcal{V}, \mathcal{A}, \mathcal{R}, \mathcal{P})$. $\mathcal{V}$ can output $\perp$ if $\mathcal{V}$ is not convinced that $\mathcal{P}$ ’s claim is valid.

$\mathcal{P}$ is a valid prover with respect to $\mathcal{V}$ if for all streams $\mathcal{A}$,

$$\Pr_{\mathcal{R}}[\text{out}(\mathcal{V}, \mathcal{A}, \mathcal{R}, \mathcal{P}) = f(\mathcal{A})] = 1.$$

We call $\mathcal{V}$ a valid verifier for f if there is at least one valid prover $\mathcal{P}$ with respect to $\mathcal{V}$, and for all provers $\mathcal{P}'$ and all streams $\mathcal{A}$,

$$\Pr_{\mathcal{R}}[\text{out}(\mathcal{V}, \mathcal{A}, \mathcal{R}, \mathcal{P}') \notin \{f(\mathcal{A}), \perp\}] \leq 1/3.$$

Essentially, this definition states that a prover who follows the protocol correctly will always convince $\mathcal{V}$, while if $\mathcal{P}$ makes any mistakes or false claims, then this will be detected with at least constant probability. In fact, for our protocols, this ‘false positive’ probability can easily be made arbitrarily small.

As our first concern in a streaming setting is the space requirements of the verifier as well as the communication cost for the protocol, we make the following definition.

Definition 1.2 We say f possesses an r -message (h, v) protocol, if there exists a valid verifier $\mathcal{V}$ for f such that:

1. $\mathcal{V}$ has access to only $O(v)$ words of working memory.
2. There is a valid prover $\mathcal{P}$ for $\mathcal{V}$ such that $\mathcal{P}$ and $\mathcal{V}$ exchange at most r messages in total, and the sum of the lengths of all messages is $O(h)$ words.

We refer to one-message protocols as *non-interactive*. We say an r -message protocol has $\lceil r/2 \rceil$ rounds.

A key step in many proof systems is the evaluation of the *low-degree extension* of some data at multiple points. That is, the data is interpreted as implicitly defining a polynomial function which agrees with the data over the range $1 \dots n$, and which can also be evaluated at points outside this range as a check. The existence of streaming verifiers relies on the fact that such low-degree extensions can be evaluated at any given location incrementally as the data is presented [17].

Input Representation. All protocols presented in this paper can handle inputs specified in a very general data stream form. Each element of the stream is a tuple (i, δ) , where $i \in [n]$ and δ is an integer (which may be negative, thereby modeling deletions). The data stream implicitly defines a *frequency vector* a , where a_i is the sum of all δ values associated with i in the stream, and the goal is to compute a function of a . Notice the function of a to be computed may interpret a as an object other than a vector, such as a matrix or a string. For example, in the MVMULT problem described below, a defines a matrix and a vector to be multiplied, and in some of the graph problems considered as extensions in Section 2, a defines the adjacency matrix of a graph.

In Sections 2 and 3, the manner in which we describe protocols may appear to assume that the data stream has been pre-aggregated into the frequency vector a (for example, in Section 3, we apply the protocol of Goldwasser *et al.* [19] to arithmetic circuits whose i 'th input wire has value a_i). It is therefore important to emphasize that in fact all of the protocols in this paper can be executed in the input model of the previous paragraph, where $\mathcal{V}$ only sees the raw (unaggregated) stream and not the aggregated frequency vector a , and there is no explicit conversion between the raw stream and the aggregated vector a . This follows from observations in [8, 17], which we describe here for completeness.

The critical observation is that in all of our protocols, the only information $\mathcal{V}$ must extract from the data stream is the evaluation of a low-degree extension of a at a random point $\mathbf{r}$, which we denote by $\text{LDE}_a(\mathbf{r})$, and this value can be computed incrementally by $\mathcal{V}$ using $O(1)$ words of memory as the raw stream is presented to $\mathcal{V}$. Crucially this is possible because, for fixed $\mathbf{r}$, the function $a \mapsto \text{LDE}_a(\mathbf{r})$ is *linear*, and thus it is straightforward for $\mathcal{V}$ to compute the contribution of each update (i, δ) to $\text{LDE}_a(\mathbf{r})$.

More precisely, we can write $\text{LDE}_a(\mathbf{r}) = \sum_{i \in [n]} a_i \chi_i(\mathbf{r})$, where χ_i is a (Lagrange) polynomial that depends only on i . Thus, $\mathcal{V}$ can compute $\text{LDE}_a(\mathbf{r})$ incrementally from the raw stream by initializing $\text{LDE}_a(\mathbf{r}) \leftarrow 0$, and processing each update (i, δ) via:

$$\text{LDE}_a(\mathbf{r}) \leftarrow \text{LDE}_a(\mathbf{r}) + \delta \chi_i(\mathbf{r}).$$

$\mathcal{V}$ only needs to store $\text{LDE}_a(\mathbf{r})$ and $\mathbf{r}$, which requires $O(1)$ words of memory. Moreover, for any i , $\chi_i(\mathbf{r})$ can be computed in $O(\log n)$ field operations, and thus $\mathcal{V}$ can compute $\text{LDE}_a(\mathbf{r})$ with one pass over the raw stream, using $O(1)$ words of space and $\log n$ field operations per update.

Problems. To focus our discussion and experimental study, we describe four key problems that capture different aspects of computation: data grouping and aggregation, linear algebra, and pattern matching. We will study how to build valid protocols for each of these problems. Throughout, let $[n] = \{0, \dots, n-1\}$ denote the universe from which data elements are drawn.

F_2 : Given a stream of m elements from $[n]$, compute $\sum_{i \in [n]} a_i^2$ where a_i is the number of occurrences of i in the stream. This is also known as the *second frequency moment*, a special case of the k th frequency moment $F_k = \sum_{i \in [n]} a_i^k$.

F_0 : Given a stream of m elements from $[n]$, compute the number of *distinct* elements, i.e. the number of i with $a_i > 0$, where again a_i is the number of occurrences of i in the stream.

MVMULT: Given a stream defining an $n \times n$ integer matrix A , and vectors $\mathbf{x}, \mathbf{b} \in \mathbb{Z}^n$, determine whether $A\mathbf{x} = \mathbf{b}$. More generally, we are interested in the case where $\mathcal{P}$ provides a vector $\mathbf{b}$ which is claimed to be $A\mathbf{x}$. This is easily handled by our protocols, since $\mathcal{V}$ can treat the provided $\mathbf{b}$ as part of the input, even though it may arrive after the rest of the input.

PMWW: Given a stream representing text $T = (t_0, \dots, t_{n-1}) \in [n]^n$ and pattern $P = (p_0, \dots, p_{q-1}) \in [n]^q$, the pattern P is said to occur at location i in t if, for every position j in P , either $p_j = t_{i+j}$ or at least one of p_j and t_{i+j} is the wildcard symbol $*$. The pattern-matching with wildcards problem is to determine the number of locations at which P occurs in T .

For simplicity, we will assume the stream length n and the universe size m are on the same order of magnitude i.e. $m = \Theta(n)$.

All four problems require linear space in the streaming model to solve exactly (although there are space-efficient approximation algorithms for the first three [28]).

Non-interactive versus Multi-round Protocols. Protocols for reliable delegation fall into two classes: non-interactive, in which a single message is sent from prover to verifier and no communication occurs in the reverse direction; and multi-round, where the two parties have a sustained conversation, possibly spanning hundreds of rounds or more. There are merits and drawbacks to each.

— *Non-interactive Advantages:* The non-interactive model has the desirable property that the prover can compute the proof and send it to the verifier (in an email, or posted on a website) for $\mathcal{V}$ to retrieve and validate at her leisure. In contrast, the multi-round case requires $\mathcal{P}$ and $\mathcal{V}$ to interact online. Due to round-trip delays, the time cost of multi-round protocols can become high; moreover, $\mathcal{P}$ may have to do substantial computation after each message. This can involve maintaining state between messages, and performing many passes over the data. A less obvious advantage is that non-interactive protocols can be repeated for different instances (e.g. searching for different patterns in PMWW) without requiring $\mathcal{V}$ to use fresh randomness. This allows the verifier to amortize much of its time cost over many queries, potentially achieving sublinear time cost per query. The reason this is possible is that in the course of a non-interactive protocol, $\mathcal{P}$ learns nothing about $\mathcal{V}$'s private randomness (assuming $\mathcal{P}$ does not learn whether $\mathcal{V}$ accepts or rejects the proof) and so we can use a union bound to bound the probability of error over multiple instances. In contrast, in the multi-round case, $\mathcal{V}$ must divulge most of its private random bits to $\mathcal{P}$ over the course of the protocol.

— *Multi-round Advantages:* The overall cost in a multi-round protocol can be lower, as most non-interactive protocols require $\mathcal{V}$ to use substantial space and read a large proof. Indeed, prior work [8, 15] has shown that space or communication must be $\Omega(\sqrt{n})$ for most non-interactive protocols [8]. Nonetheless, even for terabyte streams of data, these costs typically translate to only a few megabytes of space and communication, which is tolerable in many applications. Of more concern is that the time cost to the prover in known non-interactive protocols is typically much higher than in the interactive case, though this gap is not known to be inherent. We make substantial progress in closing this gap in prover runtime in Section 2, but this still leaves an order of magnitude difference in practice (Section 5).

1.3 Outline and Contributions

We consider non-interactive protocols first, and interactive protocols second. To begin, we describe in Section 2 how to use Fast Fourier Transform methods to engineer $\mathcal{P}$'s runtime in the F_2 protocol of [8] down from $O(n^{3/2})$ to nearly-linear time. The F_2 protocol is a key target, because (as we describe) several protocols build directly upon it. We show in Section 5 that this results in a speedup of hundreds of thousands of updates per second, bringing this protocol, as well as those that build upon it, from theory to practice.

Turning to interactive protocols, in Section 2.1 we describe an efficient instantiation of the general-purpose construction of [19]. Here, we also describe efficient protocols for specific problems of high interest including F_0 and PMWW based on an application of our implementation to carefully chosen circuits. The latter protocol enables verifiable searching (even with wildcards) in the cloud, and complements work on searching in encrypted data within the cloud (e.g. [5]). Our final contribution in this section is to demonstrate that the use of more general arithmetic gates to enhance the basic protocol of [19] allows us to significantly decrease prover time, communication cost, and message cost of these two protocols in practice.

In Section 4 we provide alternative interactive protocols for important specific problems based on a technique known as linearization; we demonstrate in Section 5 that linearization yields a protocol for F_0 in which $\mathcal{P}$ runs nearly two orders of magnitude faster than in all other known protocols for this problem. Finally, we describe our observations on implementing these different methods, including our carefully engineered implementation of the powerful general-purpose construction of [19].

2 Fast Non-interactive Proofs via Fast Fourier Transforms

In this section, we describe how to drastically speed up $\mathcal{P}$'s computation for a large class of *specialized*, non-interactive protocols. In non-interactive proofs, $\mathcal{P}$ often needs to evaluate a low-degree extension at a large number of locations, which can be the bottleneck. Here, we show how to reduce the cost of this step to near linear, via Fast Fourier Transform (FFT) methods.

For concreteness, we describe the approach in the context of a non-interactive protocol for F_2 given in [8]. Initial experiments on this protocol identified the prover's runtime as the principal bottleneck in the protocol [17]. In this implementation, $\mathcal{P}$ required $\Theta(n^{3/2})$ time, and consequently the implementation fails to scale for $n > 10^7$. Here, we show that FFT techniques can dramatically speed up the prover, leading to a protocol that easily scales to streams consisting of billions of items.

We point out that F_2 is a problem of significant interest, beyond being a canonical streaming problem. Many existing protocols in the non-interactive model are built on top of F_2 protocols, including finding the inner product and Hamming distance between two vectors [8], the MVMULT problem, solving a large class of linear programs, and graph problems such as testing connectivity and identifying bipartite perfect matchings [9, 15]. These protocols are particularly important because they all achieve provably optimal tradeoffs between space and communication costs [8]. Thus, by developing a scalable, practical protocol for F_2 , we also achieve big improvements in protocols for a host of important (and seemingly unrelated) problems.

Non-interactive F_2 and MVMULT Protocols. We first outline the protocol from [8, Theorem 4] for F_2 on an n dimensional vector. This construction yields an $(n^\alpha, n^{1-\alpha})$ protocol for *any* $0 \leq \alpha \leq 1$, i.e. it allows a tradeoff between the amount of communication and space used by $\mathcal{V}$; for brevity we describe the protocol when $\alpha = 1/2$.

Assume for simplicity that n is a perfect square. We treat the n dimensional vector as a $\sqrt{n} \times \sqrt{n}$ array

a. This implies a two-variate polynomial f over a suitably large finite field $\mathbb{F}_p$, such that

$$\forall (x, y) \in [\sqrt{n}] \times [\sqrt{n}] : f(x, y) = a_{x,y}.$$

To compute F_2 , we wish to compute

$$\sum_{x \in [\sqrt{n}], y \in [\sqrt{n}]} a_{x,y}^2 = \sum_{x \in [\sqrt{n}], y \in [\sqrt{n}]} f^2(x, y).$$

The low-degree extension f can also be evaluated at locations outside $[\sqrt{n}] \times [\sqrt{n}]$. In the protocol, the verifier $\mathcal{V}$ picks a random position $r \in \mathbb{F}_p$, and evaluates $f(r, y)$ for every $y \in [\sqrt{n}]$ ([8] shows how $\mathcal{V}$ can compute any $f(r, y)$ incrementally in constant space). The proof given by $\mathcal{P}$ is in the form of a degree $2(\sqrt{n} - 1)$ polynomial $s(X)$ which is claimed to be $\sum_{y \in [\sqrt{n}]} f(X, y)^2$. $\mathcal{V}$ uses the values of $f(r, y)$ to check that $s(r) = \sum_{y \in [\sqrt{n}]} f(r, y)^2$, and if so accepts $\sum_{x \in [\sqrt{n}]} s(x)$ as the correct answer. Clearly $\mathcal{V}$'s check will pass if s is as claimed. The proof of validity follows from the Schwartz-Zippel lemma: if $s(X) \neq \sum_{y \in [\sqrt{n}]} f(X, y)^2$ as claimed by $\mathcal{P}$, then

$$\Pr [s(r) = \sum_{y \in [\sqrt{n}]} f(r, y)^2] \leq \frac{\text{degree}(s)}{|\mathbb{F}_p|} = \frac{2(\sqrt{n} - 1)}{p}$$

where p is the size of the finite field $\mathbb{F}_p$. Thus, if $\mathcal{P}$ deviates at all from the prescribed protocol, the verifier's check will fail with high probability.

A non-interactive protocol for MVMULT uses similar ideas. Each entry in the output is the result of an inner product between two vectors: a row of matrix A and vector $\mathbf{x}$. Each of the n entries in the output can be checked independently with a variation of the above protocol, where the squared values are replaced by products of vector entries; this naive approach yields an $(n^{3/2}, n^{3/2})$ protocol for MVMULT. [15] observes that, because $\mathbf{x}$ is held constant throughout all n inner product computations, $\mathcal{V}$'s space requirements can be reduced by having $\mathcal{V}$ keep track of hashed information, rather than full vectors. The messages from $\mathcal{P}$ do not change, however, and computing low-degree extensions of the input data is the chief scalability bottleneck. This construction yields a 1-message $(n^{1+\alpha}, n^{1-\alpha})$ protocol (as in Definition 1.2) for any $0 \leq \alpha \leq 1$, and this can be shown to be optimal.

2.1 Breaking the bottleneck

Since $s(X)$ has degree at most $2\sqrt{n} - 1$ it is uniquely specified by its values at any $2\sqrt{n}$ locations. We show how $\mathcal{P}$ can quickly evaluate all values in the set

$$S := \{(x, s(x)) : x \in [2\sqrt{n}]\}.$$

Since $s(X) = \sum_{y \in [\sqrt{n}]} f(X, y)^2$, given all values in set

$$T := \{(x, y, f(x, y)) : x \in [2\sqrt{n}], y \in [\sqrt{n}]\},$$

all values in S can be computed in time linear in n . The implementation of [17] calculated each value in T independently, requiring $\Theta(n^{3/2})$ time overall. We show how FFT techniques allow us to calculate T much faster.

The task of computing T boils down to multi-point evaluation of the polynomial f . It is known how to perform fast multi-point evaluation of univariate degree t polynomials in time $O(t \log t)$, and bivariate

polynomials in subquadratic time, if the polynomial is specified by its coefficients [27]. However, there is substantial overhead in converting f to a coefficient representation. It is more efficient for us to directly work with and exchange polynomials in an implicit representation, by specifying their values at sufficiently many points.

Representing as a convolution. We are given the values of f at all points located on the $[\sqrt{n}] \times [\sqrt{n}]$ “grid”. We leverage this fact to compute T efficiently in nearly linear time by a direct application of the Fast Fourier Transform. For $(x, y) \in [\sqrt{n}] \times [\sqrt{n}]$, $f(x, y)$ is just $a_{x,y}$, which $\mathcal{P}$ can store explicitly while processing the stream. It remains to calculate $(x, y, f(x, y))$ for $\sqrt{n} \leq x < 2\sqrt{n}$. For fixed $y \in [\sqrt{n}]$, we may write $f(X, y)$ explicitly as

$$f(X, y) = \sum_{i \in [\sqrt{n}]} a_{i,y} \chi_i(X),$$

where χ_i is the Lagrange polynomial¹

$$\chi_i(j) = \prod_{x \in [\sqrt{n}] \setminus \{i\}} (j - i)(x - i)^{-1}$$

If $j \notin [\sqrt{n}]$, then we may write

$$f(j, y) = \sum_{i \in [\sqrt{n}]} h(j) b_y(i) g(j - i) \tag{1}$$

$$\text{where } b_y(i) = a_{i,y} \prod_{x \in [\sqrt{n}] \setminus \{i\}} (x - i)^{-1},$$

$$h(j) = \prod_{k=(j+1-\sqrt{n})}^j k,$$

$$\text{and } g(j - i) = (j - i)^{-1}.$$

As a result $f(j, y)$ can be computed as a circular convolution of b_y and g , scaled by $h(j)$. That is, for a fixed y , all values in the set $T_y := \{(x, y, f(x, y)) : x \in [2\sqrt{n}]\}$ can be found by computing the convolution in Equation 1, then scaling each entry by the appropriate value of $h(j)$.

Computing the Convolution. We represent b_y and g by vectors of length $2\sqrt{n}$ over a suitable field, and take the Discrete Fourier Transform (DFT) of each. The convolution is the inverse transform of the inner product of the two transforms [23, Chapter 5]. There is some freedom to choose the field over which to perform the transform. We can compute the DFT of f_y and g over the complex field $\mathbb{C}$ using $O(\sqrt{n} \log n)$ arithmetic operations via standard techniques such as the Cooley-Tukey algorithm [14], and simply reduce the final result modulo p , rounded to the nearest integer. Logarithmically many bits of precision past the decimal point suffice to obtain a sufficiently accurate result. Since we compute $O(\sqrt{n})$ such convolutions, we obtain the following result:

Theorem 2.1 *The honest prover in the F_2 protocol of [8, Theorem 4] requires $O(n \log n)$ arithmetic operations on numbers of bit-complexity $O(\log n + \log p)$.*

¹That is, the unique polynomial of degree $\sqrt{n}$ such that $\chi_i(i) = 1$, while for $j \neq i \in [\sqrt{n}]$, $\chi_i(j) = 0$. Here, the inverse is the multiplicative inverse within the field.

In practice, however, working over $\mathbb{C}$ can be slow, and requires us to deal with precision issues. Since the original data resides in some finite field $\mathbb{F}_p$, and can be represented as fixed-precision integers, it is preferable to also compute the DFT over the same field. Here, we exploit the fact that in designing our protocol, we can choose to work over *any* sufficiently large finite field $\mathbb{F}_p$.

There are two issues to address: we need that there *exists* a DFT for sequences of length $2\sqrt{n}$ (or thereabouts) in $\mathbb{F}_p$, and further that this DFT has a corresponding (*fast*) Fourier Transform algorithm. We can resolve both issues with the *Prime Factor Algorithm* (PFA) for the DFT in $\mathbb{F}_p$ [6]. The “textbook” Cooley-Turkey FFT algorithm operates on sequences whose length is a power of two. Instead, the PFA works on sequences of length $N = N_1 \times N_2 \times \dots \times N_k$, where the N_i ’s are pairwise coprime. The time cost of the transform is $O((\sum_i N_i)N)$. The algorithm is typically applied over the complex numbers, but also applies over $\mathbb{F}_p$: it works by breaking the large DFT up into a sequence of smaller DFTs, each of size N_i for some i . These base DFTs for sequences of length N_i exist for $\mathbb{F}_p$ whenever there exists a primitive N_i ’th root of unity in $\mathbb{F}_p$. This is the case whenever N_i is a divisor of $p - 1$. So we are in good shape so long as $p - 1$ has many distinct prime factors.

Here, we use our freedom to fix p , and choose $p = 2^{61} - 1$.² Notice that

$$2^{61} - 2 = 2 \times 3^2 \times 5^2 \times 7 \times 13 \times 31 \times 41 \times 61 \times 151 \times 331 \times 1321,$$

and so there are many such divisors N_i to choose from when working over $\mathbb{F}_p$. If $2\sqrt{n}$ is not equal to a factor of $p - 1$, we can simply pad the vectors f_y and g such that their lengths are factors of $2^{61} - 2$. Since $2^{61} - 2$ has many *small* factors, we never have to use too much padding: we calculated that we never need to pad any sequence of length $100 \leq N \leq 10^9$ (good for n up to 10^{18}) by more than 16% of its length. This is better than the Cooley-Tukey method, where padding can double the length of the sequence.

As an example, we can work with the length $N = 2 \times 5 \times 7 \times 9 \times 11 \times 13 = 90090$, sufficient for inputs of size $n = (N/2)^2$, which is over 10^9 . The cost scales as $(2 + 5 + 7 + 9 + 11 + 13)N = 47N$. Therefore, the PFA approach offers a substantial improvement over naive convolution in $\mathbb{F}_p$, which takes time $\Theta(N^2)$.

Parallelization. This protocol is highly amenable to parallelization. Observe that $\mathcal{P}$ performs $O(\sqrt{n})$ independent convolutions of each of length $O(\sqrt{n})$ (one for each column y of the matrix $a_{x,y}$), followed by computing $\sum_y a_{x,y}^2$ for each row x of the result. The convolutions can be done in parallel, and once complete, the sum of squares of each row can also be parallelized. This protocol also possesses a simple two-round MapReduce protocol. In the first round, we assign each column y of the matrix $a_{x,y}$ a unique key, and have each reducer perform the convolution for the corresponding column. In the second round, we assign each row x a unique key, and have each reducer compute $\sum_y a_{x,y}^2$ for its row x .

2.2 Implications

As we experimentally demonstrate in Section 5, the results of this section make practical the fundamental building block for the majority of known non-interactive protocols. Indeed, by combining Theorem 2.1 with protocols from [8, 15], we obtain the following immediate corollaries. For all graph problems considered, n is the number of nodes in the graph, and m is the number of edges.

Corollary 2.2 *1. (Extending [8, Theorem 4.3]) For any $h \cdot v \geq n$, there is an (h, v) protocol for computing the inner product and Hamming distance of two n -dimensional vectors, where $\mathcal{V}$ runs in time $O(n)$ and $\mathcal{P}$ runs in time $O(n \log n)$. The previous best runtime known for $\mathcal{P}$ was $O(h^2 v)$.*

²Arithmetic in this field can also be done quickly, see Section 5.1.

2. (Extending [15, Theorem 4]) For any $h \cdot v \geq n$, there is an (mh, v) protocol for $m \times n$ integer matrix-vector multiplication (MVMULT), where $\mathcal{V}$ runs in time $O(mn)$ and $\mathcal{P}$ runs in time $O(mn \log n)$. The best runtime known for $\mathcal{P}$ previously was $O(mh^2v)$.
3. (Extending [15, Corollary 3]) For any $h \cdot v \geq n$, there is an $O(nh, v)$ protocol for solving a linear program over n variables with n (integer) constraints and subdeterminants of polynomial magnitude, where $\mathcal{V}$ runs in time $O(n^2)$ and $\mathcal{P}$ runs in time $O(t(n) + n^2 \log n)$, where $t(n)$ is the time required to solve the linear program and its dual. The best runtime known for $\mathcal{P}$ previously was $O(t(n) + nh^2v)$.
4. (Extending [8, Theorem 5.4]) For any $h \cdot v \geq n^3$, there is an (h, v) protocol for counting the number of triangles in a graph, where $\mathcal{V}$ runs in time $O(mn)$ and $\mathcal{P}$ runs in time $O(n^3 \log n)$. The best runtime known for $\mathcal{P}$ previously was $O(h^2v)$.
5. (Extending [9, Theorem 6.6]) For any $h \cdot v \geq n^2$, $h \geq n$, there is an (h, v) protocol for graph connectivity, where $\mathcal{P}$ runs in time $O(n^2 \log n)$ and $\mathcal{V}$ runs in time $O(m)$. The best runtime known for $\mathcal{P}$ previously was $O(nh^2v)$.
6. (Extending [9, Theorem 6.5]) For any $h \cdot v \geq n^2$, $h \geq n$, there is an (h, v) protocol for bipartite perfect matching, where $\mathcal{V}$ runs in time $O(m)$ and $\mathcal{P}$ runs in time $O(t(n) + n^2 \log n)$, where $t(n)$ is the time required to find a perfect matching if one exists, or to find a counter-example (via Hall's Theorem) otherwise. The best runtime known for $\mathcal{P}$ previously was $O(t(n) + h^2v)$.

In the common case where we choose $h = v$, this represents a polynomial-speed up in $\mathcal{P}$'s runtime. For example, for the MVMULT problem, the prover's cost is reduced from $O(mn^{3/2})$ in prior work to $O(mn \log n)$.

In most cases of Corollary 2.2, $\mathcal{V}$ runs in linear time, and $\mathcal{P}$ runs in nearly linear time for dense inputs, plus the time $t(n)$ required to solve the problem in the first place, which may be superlinear. Thus, $\mathcal{P}$ pays at most a logarithmic factor overhead in solving the problem “verifiably”, compared to solving the problem in a non-verifiable manner.

3 A General Approach: Multi-round Protocols Via Circuit Checking

In this section, we study *interactive* protocols, and describe how to efficiently instantiate the powerful framework due to Goldwasser, Kalai, and Rothblum for verifying arbitrary computations³.

A standard approach to verified computation developed in the theoretical literature is to verify properties of circuits that compute the desired function [18, 19, 31]. One of the most promising of these is due to Goldwasser *et al.*, which proves the following result:

Theorem 3.1 [19] *Let f be a function over an arbitrary field $\mathbb{F}$ that can be computed by a family of $O(\log S(n))$ -space uniform arithmetic circuits (over $\mathbb{F}$) of fan-in 2, size $S(n)$, and depth $d(n)$. Then, assuming unit cost for transmitting or storing a value in $\mathbb{F}$, f possesses a $(\log S(n), d(n) \log S(n))$ -protocol requiring $O(d(n) \log S(n))$ rounds. $\mathcal{V}$ runs in time $(n + d(n)) \text{polylog}(S(n))$ and $\mathcal{P}$ runs in time $\text{poly}(S(n))$.*

Here, an arithmetic circuit over a field $\mathbb{F}$ is analogous to a boolean circuit, except that the inputs are elements of $\mathbb{F}$ rather than boolean values, and the gates of the circuit compute addition and multiplication over $\mathbb{F}$. We address how to realize the protocol of Theorem 3.1 efficiently. Specifically, we show three

³We are indebted to these authors for sharing their working draft of the full version of [19], which provides much greater detail than is possible in the conference presentation.

technical results. The first two results, Theorems 3.2 and 3.3, state that for *any* log-space uniform circuit, the honest prover in the protocol of Theorem 3.1 can be made to run in time nearly linear in the size of the circuit, with a streaming verifier who uses only $O(\log S(n))$ words of memory. Thus, these results guarantee a highly efficient prover and a space-efficient verifier. In streaming contexts, where $\mathcal{V}$ is more space-constrained than time-constrained, this may be acceptable. Moreover, Theorem 3.3 states that $\mathcal{V}$ can perform the time-consuming part of its computation in a data-independent non-interactive preprocessing phase, which can occur offline before the stream is observed.

Our third result, Theorem 3.4 makes a slightly stronger assumption but yields a stronger result: it states that under very mild conditions on the circuit, we can achieve a prover who runs in time nearly linear in the size of the circuit, and a verifier who is *both* space- and time-efficient.

Before stating our theorems, we sketch the main techniques needed to achieve the efficient implementation, with full details in Appendix A. We also direct the interested reader to the source code of our implementations [16]. The remainder of this section is intended to be reasonably accessible to readers who are familiar with the sum-check protocol [33, 25], but not necessarily with the protocol of [19].

3.1 Engineering an Efficient Prover

In the protocol of [19], $\mathcal{V}$ and $\mathcal{P}$ first agree on a depth d circuit C of gates with fan-in 2 that computes the function of interest; C is assumed to be in layered form (this assumption blows up the size of the circuit by at most a factor of d , and we argue that it is unrestrictive in practice, as the natural circuits for all four of our motivating problems are layered, as well as for a variety of other problems described in Appendix A). $\mathcal{P}$ begins by claiming a value for the output gate of the circuit. The protocol then proceeds iteratively from the output layer of C to the input layer, with one iteration for each layer. For presentation purposes, assume that all layers of the circuit have n gates, and let $v = \log n$.

At a high level, in iteration 1, $\mathcal{V}$ reduces verifying the claimed value of the output gate to computing the value of a certain $3v$ -variate polynomial f_1 at a random point $r^{(1)} \in \mathbb{F}^{3v}$. The iterations then proceed inductively over each layer of gates: in iteration $i > 1$, $\mathcal{V}$ reduces computing $f_{i-1}(r^{(i-1)})$ for a certain $3v$ -variate polynomial f_{i-1} to computing $f_i(r^{(i)})$ for a random point $r^{(i)} \in \mathbb{F}_p^{3v}$. Finally, in iteration d , $\mathcal{V}$ must compute $f_d(r^{(d)})$. This happens to be a function of the input alone (specifically, it is an evaluation of a low-degree extension of the input), and $\mathcal{V}$ can compute this value in a streaming fashion, without assistance, even if only given access to the raw (unaggregated) data stream, as described in Section 1.2. If the values agree, then $\mathcal{V}$ is convinced of the correctness of the output.

We abstract the notion of a “wiring predicate”, which encodes which pairs of wires from layer $i - 1$ are connected to a given gate at layer i . Each iteration i consists of an application of the standard *sum-check protocol* [25, 33] to a $3v$ -variate polynomial f_i based on the wiring predicate. There is some flexibility in choosing the specific polynomial f_i to use. This is because the definition of f_i involves a low-degree extension of the circuit’s wiring predicate, and there are many such low-degree extensions to choose from.

A polynomial is said to be *multilinear* if it has degree at most one in each variable. The results in this section rely critically on the observation that the honest prover’s computation in the protocol of [19] can be greatly simplified if we use the multilinear extension of the circuit’s wiring predicate.⁴ Details of this observation follow.

As already mentioned, at iteration i of the protocol of [19], the sum-check protocol is applied to the $3v$ -variate polynomial f_i . In the j ’th round of this sum-check protocol, $\mathcal{P}$ is required to send the *univariate*

⁴There are other reasons why using the multilinear extension is desirable. For example, the communication cost of the protocol is proportional to the degree of the extension used.

polynomial

$$g_j(X_j) = \sum_{(x_{j+1}, \dots, x_{3v}) \in \{0,1\}^{3v-j}} f_i(r_1^{(i)}, \dots, r_{j-1}^{(i)}, X_j, x_{j+1}, \dots, x_{3v}).$$

The sum defining g_j involves as many as n^3 terms, and thus a naive implementation of $\mathcal{P}$ would require $\Omega(n^3)$ time per iteration of the protocol. However, we observe that if the multilinear extension of the circuit's wiring predicate is used in the definition of f_i , then each gate at layer $i - 1$ contributes to exactly one term in the sum defining g_j , as does each gate at layer i . Thus, the polynomial g_j can be computed with a *single* pass over the gates at layer $i - 1$, and a single pass over the gates at layer i . As the sum-check protocol requires $O(v) = O(\log S(n))$ messages for each layer of the circuit, $\mathcal{P}$ requires logarithmically many passes over each layer of the circuit in total.

A complication in applying the above observation is that $\mathcal{V}$ must process the circuit in order to pull out information about its structure necessary to check the validity of $\mathcal{P}$'s messages. Specifically, each application of the sum-check protocol requires $\mathcal{V}$ to evaluate the multilinear extension of the wiring predicate of the circuit at a random point. Theorem 3.2 follows from the fact that for any log-space uniform circuit, $\mathcal{V}$ can evaluate the multilinear extension of the wiring predicate at any point using space $O(\log S(n))$. We present detailed proofs and discussions of the following theorems in Appendix A.

Theorem 3.2 *For any log-space uniform circuit of size $S(n)$, $\mathcal{P}$ requires $O(S(n) \log S(n))$ time to implement the protocol of Theorem 3.1 over the entire execution, and $\mathcal{V}$ requires space $O(\log S(n))$.*

Moreover, because the circuit's wiring predicate is independent of the input, we can separate $\mathcal{V}$'s computation into an offline non-interactive preprocessing phase, which occurs before the data stream is seen, and an online interactive phase which occurs after both $\mathcal{P}$ and $\mathcal{V}$ have seen the input. This is similar to [19, Theorem 4], and ensures that $\mathcal{V}$ is space-efficient (but may require time $\text{poly}(S(n))$) during the offline phase, and that $\mathcal{V}$ is *both* time- and space-efficient in the online interactive phase. In order to determine which circuit to use, $\mathcal{V}$ does need to know (an upper bound on) the length of the input during the preprocessing phase.

Theorem 3.3 *For any log-space uniform circuit of size $S(n)$, $\mathcal{P}$ requires $O(S(n) \log S(n))$ time to implement the protocol of Theorem 3.1 over the entire execution. $\mathcal{V}$ requires space $O(d(n) \log S(n))$ and time $O(\text{poly}(S(n)))$ in a non-interactive, data-independent preprocessing phase, and only requires space $O(d(n) \log S(n))$ and time $O(n \log n + d(n) \log S(n))$ in an online interactive phase, where the $O(n \log n)$ term is due to the time required to evaluate the low-degree extension of the input at a point.*

Finally, Theorem 3.4 follows by assuming $\mathcal{V}$ can evaluate the multilinear extension of the wiring predicate quickly. A formal statement of Theorem 3.4 is in Appendix A. We believe that the hypothesis of Theorem 3.4 is extremely mild, and we discuss this point at length in Appendix A, identifying a diverse array of circuits to which Theorem 3.4 applies. Moreover, the solutions we adopt in our circuit-checking experiments for F_2 , F_0 , and PMWW correspond to Theorem 3.4, and are both space- and time-efficient for the verifier.

Theorem 3.4 (informal) *Let C be any log-space uniform circuit of size $S(n)$ and depth $d(n)$, and assume there exists a $O(\log S(n))$ -space, $\text{poly}(\log S(n))$ -time algorithm for evaluating the multilinear extension of C 's wiring predicate at a point. Then in order to implement the protocol of Theorem 3.1 applied to C , $\mathcal{P}$ requires $O(S(n) \log S(n))$ time, and $\mathcal{V}$ requires space $O(\log S(n))$ and time $O(n \log n + d(n) \text{poly}(\log S(n)))$, where the $O(n \log n)$ term is due to the time required to evaluate the low-degree extension of the input at a point.*

3.2 Circuit Design Issues

The protocol of [19] is described for arithmetic circuits with addition (+) and multiplication gates ($\times$). This is sufficient to prove the power of this system, since any efficiently computable boolean function on boolean inputs can be computed by an (asymptotically) small arithmetic circuit. Typically such arithmetic circuits are obtained by constructing a *boolean* circuit (with AND, OR, and NOT gates) for the function, and then “arithmetizing” the circuit [2, Chapter 8]. However, we strive not just for asymptotic efficiency, but genuine practicality, and the factors involved can grow quite quickly: every layer of (arithmetic) gates in the circuit adds $3v$ rounds of interaction to the protocol. Hence, we further explore optimizations and implementation issues.

Extended Gates. The circuit checking protocol of [19] can be extended with any gates that compute low-degree polynomial functions of their inputs. If g is a polynomial of degree j , we can use gates computing $g(x)$; this increases the communication complexity in each round of the protocol by at most $j - 2$ words, as $\mathcal{P}$ must send a degree- j polynomial, rather than a degree-2 polynomial.

The low-depth circuits we use to compute functions of interest (specifically, F_0 and PMWW) make use of the function $f(x) = x^{p-1}$. Using only $+$ and $\times$ gates, they require depth about $\log_2 p$. If we also use gates computing $g(x, y) = x^j y^j$ for a small j , we can reduce the depth of the circuits to about $\log_{2j} p$; as the number of rounds in the protocol of [19] depends linearly on the depth of the circuit, this reduces the number of rounds by a factor of about $\log_2 p / \log_{2j} p = 1 / \log_{2j} 2$. At the same time this increases the communication cost of each round by a factor of (at most) $j - 2$. We can optimize the choice of j . In our experiments, we use $j = 4$ (so $g(x, x)$ is x^8) and $j = 8$ ($g(x, x) = x^{16}$) to simultaneously reduce the number of messages by a factor of 3, and the communication cost and prover runtime by significant factors as well.

Another optimization is possible. All four specific problems we consider, F_2 , F_0 , PMWW, and MV-MULT, eventually compute the sum of a large number of values. Let f be the low-degree extension of the values being summed. For functions of this form, $\mathcal{V}$ can use a single *sum-check protocol* [2, Chapter 8] to reduce the computation of the sum to computing $f(r)$ for a random point r . $\mathcal{V}$ can then use the protocol of [19] to delegate computation of $f(r)$ to $\mathcal{P}$. Conceptually, this optimization corresponds to replacing a binary tree of addition gates in an arithmetic circuit C with a single $\oplus$ gate with large fan-in, which sums all its inputs. This optimization can reduce the communication cost and the number of messages required by the protocol.

General Circuit Design. The circuit checking approach can be combined with existing compilers, such as that in the Fairplay system [26], that take as input a program in a high-level programming language and output a corresponding boolean circuit. This boolean circuit can then be arithmetized and “verified” by our implementation; this yields a full-fledged system implementing statistically-secure verifiable computation. However, this system is likely to remain impractical even though the prover $\mathcal{P}$ can be made to run in time linear in the size of the arithmetic circuit. For example, in most hardware, one can compute the sum of two 32-bit integers x and y with a single instruction. However, when encoding this operation into a boolean circuit, it is unclear how to do this with depth less than 32. At $3 \log n$ rounds per circuit layer, for reasonable parameters, single additions can turn into thousands of rounds.

The protocols in Section 3.3 avoid this by avoiding boolean circuits, and instead view the input directly as elements over $\mathbb{F}_p$. For example, if the input is an array of 32-bit integers, then we view each element of the array as a value of $\mathbb{F}_p$, and calculating the sum of two integers requires a single depth-1 addition gate, rather than a depth-32 boolean circuit. However, this approach seems to severely limit the functionality that can be implemented. For instance, we know of no compact arithmetic circuit to test whether $x > y$ when

viewing x and y as elements of $\mathbb{F}_p$. Indeed, if such a circuit for this function existed, we would obtain substantially improved protocols for F_0 and PMWW.

This polylogarithmic blowup in circuit depth compared to input size appears inherent in any construction that encodes computations as arithmetic circuits. Therefore, the development of general purpose protocols that avoid this representation remains an important direction for future work.

3.3 Efficient Protocols For Specific Problems

We obtain *interactive* protocols for our problems of interest by applying Theorem 3.1 to carefully chosen arithmetic circuits. These are circuits where each gate executes a simple arithmetic operation on its inputs, such as addition, subtraction, or multiplication. For the first three problems, there exist specialized protocols; our purpose in describing these protocols here is to explore how the general construction performs when applied to specific functions of high interest. However, for PMWW, the protocol we describe here is the first of its kind.

For each problem, we describe a circuit which exploits the arithmetic structure of the finite field over which they are defined. For the latter three problems, this involves an interesting use of Fermat's Little Theorem. These circuits lend themselves to extensions of the basic protocol of [19] that achieve quantitative improvements in all costs; we demonstrate the extent of these improvements in Section 5.

Protocol for F_2 : The arithmetic circuit for F_2 is quite straightforward: the first level computes the square of input values, then subsequent levels sum these up pairwise to obtain the sum of all squared values. The total depth d is $O(\log n)$. This implies a $O(\log^2 n)$ message $(\log^2 n, \log^2 n)$ protocol (as per Definition 1.2).

Protocol for F_0 : We describe a succinct arithmetic circuit over $\mathbb{F}_p$ that computes F_0 . When p is a prime larger than n , Fermat's Little Theorem (FLT) implies that for $x \in \mathbb{F}_p$, $x^{p-1} = 1$ if and only if $x \neq 0$. Consider the circuit that, for each coordinate i of the input vector a , computes each a_i^{p-1} via $O(\log p)$ multiplications, and then sums the results. This circuit has total size $O(n \log p)$ and depth $O(\log p)$. Applying the protocol of [19] to this circuit, we obtain a $(\log n \log p, \log n)$ protocol where $\mathcal{P}$ runs in time $O(n \log n \log p)$.

Protocol for MVMULT: The first level of the circuit computes $A_{ij}\mathbf{x}_i$ for all i, j , and subsequent levels sum these to obtain $\sum_j A_{ij}\mathbf{x}_i$. Then we use FLT to ensure that $\sum_j A_{ij}\mathbf{x}_i = b_i$ for all i , via

$$\sum_i \left(\left(\sum_j A_{ij}\mathbf{x}_i \right) - b_i \right)^{p-1}.$$

The input is as claimed if this final output of the circuit is 0 (i.e. it counts the number of entries of $\mathbf{b}$ that are incorrect). This circuit has depth $O(\log p)$ and size $O(n^2 \log p)$, and we therefore obtain an $(n + \log p \log n, \log n)$ protocol requiring $O(\log p \log n)$ -rounds, where $\mathcal{P}$ runs in time $O(n^2 \log p \log n)$.

Protocol for PMWW: To handle wildcards in both T (of length n) and P (of length q), we replace each occurrence of the wildcard symbol with 0; [13] notes that the pattern occurs at location i of T if and only if

$$I_i := \sum_{j=0}^{q-1} t_{i+j} p_j (t_{i+j} - p_j)^2 \neq 0.$$

Thus, by FLT, it suffices to compute $\sum_{i=0}^n I_i^{p-1}$, which can be done naively by an arithmetic circuit of size $O(nq + n \log p)$ and depth $O(\log p + \log q)$. We obtain a $(\log n \log p, \log n)$ protocol where $\mathcal{P}$ runs in time $O(n \log n(q + \log p))$.

For large q , a further optimization is possible: the vector I can be written as the sum of a constant number of circular convolutions. Such convolutions can be computed efficiently using Fourier techniques in time $O(n \log q)$ and, importantly, appropriate FFT and inverse FFT operations can be implemented via arithmetic circuits. Thus, for q larger than $\log p$, we can reduce the circuit size (and hence $\mathcal{P}$'s runtime) in this way, rather than by naively computing each entry of I independently.

4 Multi-Round Protocols via Linearization

In this section, we show how the technique of *linearization* can improve upon the general approach of Section 2.1 for some important functions. Specifically, this technique can be applied to multi-round protocols which would otherwise require polynomials of very high degree to be communicated. We show this in the context of new multi-round protocols for F_0 and PMWW and we later empirically observe that our new protocol achieves a speed up of two orders of magnitude over existing protocols for F_0 , as well as an order of magnitude improvement in communication cost.

Existing approaches for F_0 in the multi-round setting are based on generalizations of the multi-round protocol for F_2 [17]. As described in [17], directly applying this approach is problematic: the central function in F_0 maps non-zero frequencies to 1 while keeping zero frequencies as zero. Expressed as a polynomial, this function has degree m (an upper bound on the frequency of any item), which translates into a factor of m in the communication required and the time cost of $\mathcal{P}$. However, this cost can be reduced to F_∞ , where F_∞ denotes the maximum number of times any item appears in the stream. Further, if both $\mathcal{P}$ and $\mathcal{V}$ keep a buffer of b input items, they can eliminate duplicate items within the buffer, and so ensure that $F_\infty \leq m/b$. This leads to an $O(\log n)$ message, $(\log n, F_\infty \log n)$ multi-round protocol with $\mathcal{P}$'s runtime being $O(F_\infty^2 n \log n)$ [17]. This protocol trades off increased communication for a quadratic improvement in the number of rounds of communication required compared to the protocol outlined in Section 3.3 above.

4.1 Linearization Set-up

In this section we describe a new multi-round protocol for F_0 , and later explain how it can be modified for PMWW. This protocol has similar asymptotic costs as that obtained in Section 3.3, but in practice achieves close to two orders of magnitude improvement in $\mathcal{P}$'s runtime. The core idea is to represent the data as a large binary vector indicating when each item occurs in the stream. The protocol simulates progressively merging time ranges together to indicate which items occurred within the ranges. Directly verifying this computation would hit the same roadblock indicated above: using polynomials to check this would result in polynomials of high degree, dominating the cost. So we use a “linearization” technique, which ensures that the degree of the polynomials required stays low, at the cost of more rounds of interaction. This uses ideas of Shen [34] as presented in [2, Chapter 8].

As usual, we work over a finite field with p elements, $\mathbb{F}_p$. The input implicitly defines an $n \times m$ matrix A such that $A_{i,j} = 1$ if the j 'th item of the stream equals i , and $A_{i,j} = 0$ otherwise.

Working over the Boolean Hypercube. A key first step is to define an indexing structure based on the d -dimensional Boolean hypercube, so every input point is indexed by a d bit binary string, which is the (binary) concatenation of a $\log n$ bit string i and a $\log m$ bit string j . We view A as a function from $\{0, 1\}^d$ to $\{0, 1\}$ via $(x_1, \dots, x_d) \mapsto A_{(x_1, \dots, x_d)}$. Let f be the unique multilinear polynomial in d variables such that $f(x_1, \dots, x_d) = A_{(x_1, \dots, x_d)}$ for all $(x_1, \dots, x_d) \in \{0, 1\}^d$, i.e. f is the *multilinear extension* of the function on $\{0, 1\}^d$ implied by A .

The only information that the verifier $\mathcal{V}$ needs to keep track of is the value of f at a random point. That is, $\mathcal{V}$ chooses a random vector $\mathbf{r} = (r_1, \dots, r_d) \in \mathbb{F}_p^d$. It is efficient for $\mathcal{V}$ to compute $f(\mathbf{r})$ as $\mathcal{V}$ observes the stream which defines A (and hence f): when the j 'th update is item i , this translates to the vector $\mathbf{v} = (i, j) \in \{0, 1\}^d$. The necessary update is of the form $f(\mathbf{r}) \leftarrow f(\mathbf{r}) + \chi_{\mathbf{v}}(\mathbf{r})$, where $\chi_{\mathbf{v}}$ is the unique polynomial that is 1 at $\mathbf{v}$ and 0 everywhere else in $\{0, 1\}^d$. For this, $\mathcal{V}$ only needs to store $\mathbf{r}$ and the current value of $f(\mathbf{r})$.

Linearization and Arithmetized Boolean Operators. We use three operators Π , Π and L on polynomials g , defined as follows:

$$\begin{aligned}\Pi_k g(X_1, \dots, X_k) &= g(X_1, \dots, X_{k-1}, 0) + g(X_1, \dots, X_{k-1}, 1) \\ &\quad - g(X_1, \dots, X_{k-1}, 0) \cdot g(X_1, \dots, X_{k-1}, 1). \\ \Pi_k g(X_1, \dots, X_k) &= g(X_1, \dots, X_{k-1}, 0) \cdot g(X_1, \dots, X_{k-1}, 1). \\ L_i g(X_1, \dots, X_k) &= X_i \cdot g(X_1, \dots, X_{i-1}, 1, X_{i+1}, \dots, X_k) \\ &\quad + (1 - X_i) \cdot g(X_1, \dots, X_{i-1}, 0, X_{i+1}, \dots, X_k).\end{aligned}$$

Π and Π generalize the familiar “OR” and “AND” operators, respectively. Thus, if g is a k -variate polynomial of degree at most j in each variable, $\Pi_k(g)$ and $\Pi_k(g)$ are $k - 1$ -variate polynomials of degree at most $2j$ in each variable. They generalize Boolean operators in the sense that if $g(X_1, \dots, X_{k-1}, 0) = x$ and $g(X_1, \dots, X_{k-1}, 1) = y$, and x, y are both 0 or 1, then

$$\begin{aligned}(\Pi_k g)(X_1, \dots, X_k) &= 1 \quad \text{iff } x = 1 \text{ or } y = 1, \\ \text{and } (\Pi_k g)(X_1, \dots, X_k) &= 1 \quad \text{iff } x = 1 \text{ and } y = 1.\end{aligned}$$

L is a *linearization* operator. If g is a k -variate polynomial, $L_i(g)$ is a k -variate polynomial that is linear in variable X_i . L_i operations are used to control the degree of the polynomials that arise throughout the execution of our protocol. Since $x^j = x$ for all $j \geq 1, x \in \{0, 1\}$, $L_i(g)$ agrees with $g(\cdot)$ on all values in $\{0, 1\}^k$.

Throughout, when applying a sequence of operations to a polynomial to obtain a new one, the operations are applied “right-to-left”. For example, we write the $k - 1$ variate polynomial

$$(L_1(L_2 \dots (L_{k-1}(\Pi_k g)))) \text{ as } L_1 L_2 \dots L_{k-1} \Pi_k g.$$

Rewriting F_0 and PMWW. For F_2 and MVMULT there is little need for linearization: the polynomials generated remain of low-degree, so the multi-round protocols described in [17, 15] already suffice. But linearization can help with F_0 and PMWW.

Thinking of the input as a matrix A as defined above, we can compute F_0 by repeatedly taking the columnwise-OR of adjacent column pairs to end up with a vector which indicates whether item i appeared in the stream, then repeatedly summing adjacent entries to get the number of distinct elements. When representing these operations as polynomials, we make additional use of linearization operations to control the degree of the polynomials that arise. Using the properties of the operations Π and L_i described above and rewriting in terms of the hypercube, it can be seen that

$$F_0(\mathbf{a}) = \sum_{x_1=0}^1 \dots \sum_{x_k=0}^1 L_{k_1} L_{k_1-1} \dots L_1 \Pi_{k_1+1} \quad L_{k_1+1} L_{k_1} \dots L_1 \Pi_{k_1+2} \dots L_{d-1} L_{d-2} \dots L_1 \Pi_d f \quad (2)$$

because this expression only involves variables and values in $\{0, 1\}$. The size of this expression is $\frac{3d^2+3d}{2} = O(\log^2 n)$.

The case for PMWW is similar. Assume for now that the pattern length q is a power of two (if not, it can be padded with trailing wildcards). We now consider the input to define a matrix A of size $2n \times qn$, such that $A_{2i, qj+k(q-1)} = 1$ if the j 'th item of the stream equals i , for all $0 \leq k \leq q-1$, and $A_{2i-1, qj+2k} = 1$ if the k 'th character of the pattern equals i , for all $0 \leq j \leq n-1$. Wildcards in the pattern or the text are treated as occurrences of all characters in the alphabet at that location. The problem is solved over this matrix A by first taking the column-wise “AND” of adjacent columns: this leaves 1 where a text character matches a pattern for a certain offset. We then take column-wise “OR”s of adjacent columns $\log n$ times: this collapses the alphabet. Taking row-wise “AND”s of adjacent rows $\log q$ times leaves an indicator vector whose i th entry is 1 iff the pattern occurs at location i in the text. Summing the entries in this vector provides the required answer. Using linearization to bound the degree of Π and Π operators, we again obtain an expression of size $O(\log^2 n)$.

4.2 Protocols Using Linearization

Given an expression in the form of (2), we now give an inductive description of the protocol. Conceptually, each round we ask the prover to “strip off” the left-most remaining operation in the expression. In the process, we reduce a claim by $\mathcal{P}$ about the old expression to a claim about the new, shorter expression. Eventually, $\mathcal{V}$ is left with a claim about the value of f at a random point (specifically, at $\mathbf{r}$), which $\mathcal{V}$ can check against her independent evaluation of $f(\mathbf{r})$.

More specifically, suppose for some polynomial $g(X_1, \dots, X_j)$, the prover can convince the verifier that $g(a_1, a_2, \dots, a_j) = C$ with probability 1 for any $(a_1, a_2, \dots, a_j, C)$ where this is true, and probability less than ϵ when it is false. Let $U(X_1, X_2, \dots, X_l)$ be any polynomial on l variables obtained as

$$U(X_1, X_2, \dots, X_l) = \mathcal{O}g(X_1, \dots, X_j),$$

where $\mathcal{O}$ is one of $\sum_{x_i=0}^1$, $\Pi_{x_i=0}^1$, $\Pi_{x_i=1}^1$ or L_i for some variable i . (Thus l is $j-1$ in the first three cases and j in the last). Let m be an upper bound (known to the verifier) on the degree of U with respect to X_i . In our case, $m \leq 2$ because of the inclusion of L_i operations in between every Π and Π operation. We show how $\mathcal{P}$ can convince $\mathcal{V}$ that $U(a_1, a_2, \dots, a_l) = C'$ with probability 1 for any $(a_1, a_2, \dots, a_j, C')$ for which it is true and with probability at most $\epsilon + d/p$ when it is false. By renaming variables if necessary, assume $i = 1$. The verifier's check is as follows.

Case 1: $\mathcal{O} = \sum_{x_1=0}^1$. $\mathcal{P}$ provides a degree-1 polynomial $s(X_1)$ that is supposed to be $g(X_1, a_2, \dots, a_j)$. $\mathcal{V}$ checks if $s(0) + s(1) = C'$. If not, $\mathcal{V}$ rejects. If so, $\mathcal{V}$ picks a random value $a \in \mathbb{F}_p$ and asks $\mathcal{P}$ to prove $s(a) = g(a, a_2, \dots, a_j)$. If it is one of the final d rounds, $\mathcal{V}$ chooses a to be the corresponding entry of $\mathbf{r}$.

Case 2: $\mathcal{O} = \Pi_{x_1=0}^1 X$ or $\mathcal{O} = \Pi_{x_1=1}^1 X$. We do the same as in Case 1, but replace $s(0) + s(1)$ with $s(0) + s(1) - s(0)s(1)$ in the case of Π , or $s(0)s(1)$ in the case of Π .

Case 3: $\mathcal{O} = L_1$. $\mathcal{P}$ wishes to prove that $U(a_1, a_2, \dots, a_k) = C'$. $\mathcal{P}$ provides a degree-2 polynomial $s(X_1)$ that is supposed to be $g(X_1, a_2, \dots, a_k)$. We refer to this as “unbinding the variable” because previously X_1 was “bound” to value a_1 , but now X_1 is free. $\mathcal{V}$ checks that $a_1 s(0) + (1 - a_1) s(1) = C'$. If not, $\mathcal{V}$ rejects. If so, $\mathcal{V}$ picks random $a \in \mathbb{F}_p$ and asks $\mathcal{P}$ to prove $s(a) = g(a, a_2, \dots, a_k)$ (or if it is the final round, $\mathcal{V}$ simply checks that $s(a) = f(\mathbf{r})$).

The proof of correctness follows by using the observation that if $s(X_1)$ is not the right polynomial, then with probability $1 - m/p$, $\mathcal{P}$ must prove an incorrect statement at the next round (this is an instance of

Problem	Gates	Size (gates)	$\mathcal{P}$ time (s)	Rounds	Communication (KBs)	$\mathcal{V}$ time (s)
F_2	$+, \times$	0.4M	8.5	986	11.5	.01
F_2	$+, \times, \oplus$	0.2M	6.5	118	2.5	.01

Table 1: Circuit checking results with $n = 2^{17}$.

Schwartz-Zippel polynomial equality testing procedure [30]). The total probability of error is given by a union bound on the probabilities in each round, $O(\log^2 n/p)$.

Analysis of protocol costs. Recall that both F_0 and PMwW can be written as an expression of size $O(\log^2 n)$ operators, where linearization bounds the degree in any variable. Under the above procedure, the verifier need only store $\mathbf{r}$, $f(\mathbf{r})$, the current values of any “bound” variables, and the most recent value of $s(a)$. In total, this requires space $O(\log n)$. There are $O(\log^2 n)$ rounds, and in each round a polynomial of degree at most two is sent from $\mathcal{P}$ to $\mathcal{V}$. Such a polynomial can be represented with at most 3 words, so the total communication is $O(\log^2 n)$. Hence we obtain $(\log^2 n, \log n)$ -protocols for F_0 and PMwW.

As the stream is being processed the verifier has to update $f(\mathbf{r})$. The updates are very simple, and processing each update requires $O(d) = O(\log n)$ time. There is a slight overhead in PMwW, where each update in the stream requires the verifier to propagate q updates to f (assuming an upper bound on q is fixed in advance), taking $O(q)$ time. However, it seems plausible that these costs could be optimized further.

The prover has to store a description of the stream, which can be done in space $O(n)$. The prover can be implemented to require $O(n \log^2 n)$ time: essentially, each round of the proof requires at most one pass over the stream data to compute the required functions. For brevity, we omit a detailed description of the implementation, the source code of which is available at [16].

Theorem 4.1 *For any function which can be written as a concatenation of $\log n$ (binary) operators drawn from Σ , Π and $\mathbb{I}$ over inputs of size n , there is a $\log^2 n$ round $(\log^2 n, \log n)$ protocol, where $\mathcal{P}$ takes time $O(n \log^2 n)$, and $\mathcal{V}$ takes time $O(\log^2 n)$ to run the protocol, having computing the LDE of the input.*

Thus we can invoke this theorem for both F_0 and PMwW, obtaining $\log^2 n$ round $(\log^2 n, \log n)$ protocols for both.

5 Experimental Evaluation

We performed a thorough experimental study to evaluate the potential practical effectiveness of existing protocols and our new ones. We summarize our findings as follows.

- The costs of our implementation of the general-purpose circuit-checking protocol described in Section 3 are extremely attractive, with the exception of $\mathcal{P}$ ’s runtime. The prover takes minutes to operate

on input of size around 10^5 : ideally, this would take seconds. The extensions we propose to the basic protocol of [19] (such as extra types of gates) result in significant quantitative improvements for our benchmark problems. We are optimistic about the prospects for further enhancements and parallelization to make practical general-purpose verification a reality.

- Fine-tuned protocols for specific problems can improve over the general approach by several orders of magnitude. Specifically, we found that extremely practical *non-interactive* protocols processing hundreds of thousands of updates per second are achievable for a very large class of problems, but only by using the methods described in Section 2. We also found that the linearization technique results in significantly improved interactive protocols for F_0 when compared to the more general circuit-checking approach.
- Finally, we demonstrate that the non-interactive protocols are extremely amenable to parallelization, and we believe that this makes them an attractive option for practical use.

In all of our experiments, the verifier requires significantly less space than that required to solve the problem without a prover, and requires about the same time as that required to solve the problem without a prover if given enough fast memory to store the whole input. Indeed, we found that in all of our protocols memory accesses are the speed bottleneck in both $\mathcal{V}$'s computation and in the computation required to solve the problem without a prover.

Moreover, our circuit-checking results demonstrate that if we were to run our implementation on problems requiring superlinear time to solve, then $\mathcal{V}$ would save significant time as well as space (compared to solving the problem without a prover). Indeed, except for circuits with very high (i.e., linear) depth, $\mathcal{V}$'s runtime in our circuit-checking implementation is grossly dominated by the time required to perform an LDE computation via a single streaming pass over the input. The verification time, excluding this cost, is essentially negligible.

5.1 Implementation Details

All implementations were done in C++: we simulated the computations of both parties, and measured the time and resources consumed by the protocols. Our programs were compiled with g++ using the -O3 optimization flag. For the data, we generated synthetic streams in which each item was picked uniformly at random from the universe, or in which frequencies of each item were chosen uniformly at random in the range $[0, 1000]$. The choice of data does not affect the runtimes, which depend only on the amount of data and not its content. Similarly the security guarantees do not depend on the data, but on the random choices of the verifier. All computations are over the field of size $p = 2^{61} - 1$, implying a very low probability of the verifier being fooled by a dishonest prover.

We evaluated the protocols on a multi-core machine with 64-bit AMD Opteron processors and 32 GB of memory available. Our scalability results primarily use a single core, but we also show results for parallel operation. The large amount of memory allowed us to experiment with universes of size several billion, with the prover able to store the full data in memory. We measured the time for $\mathcal{V}$ to compute the check information from the stream, for $\mathcal{P}$ to generate the proof, and for $\mathcal{V}$ to verify the proof. We also measured the space required by $\mathcal{V}$, and the size of the proof provided by $\mathcal{P}$.

Choice of Field Size. While all the protocols we implemented work over arbitrary finite fields, our choice of $\mathbb{F}_p$ with $p = 2^{61} - 1$ proves ideal for engineering practical protocols. First, the field size is large enough to provide a minuscule probability of error (which is proportional to $1/p$), but small enough that any field

Figure 1: Experimental Results for both multi-round and non-interactive F_2 protocols.

element can be represented with a single 64-bit data type. By using native types, we achieve a speedup of several factors. Second, reducing modulo p can be done with a bit shift, a bit-wise AND operation, and an addition [35]. We experienced a speedup of nearly an order of magnitude by switching to this specialized “mod” operation rather than using “% p” operation in C++. Finally, the use of this particular field allows us to apply FFT techniques, as described in in Section 2 (recall $2^{61} - 2$ has many small prime factors).

Correctness of protocols. In the protocols we study, the verifier’s checks of the prover’s claims are always very simple to implement: in many cases, each check takes a single line of code to ensure that the previous message is consistent with the new message⁵. Consequently, it is not difficult to implement the verifier in a bug-free manner, and once this is the case, the verifier’s implementation serves as an independent check on the prover’s implementation. This is because the verifier detects (with high probability) *any* deviations from the prescribed protocol, and in particular $\mathcal{V}$ detects deviations due to an incorrect prover. Thus, we are confident in the correctness of our implementations. More generally, this property can help in the testing and debugging of future implementations.

5.2 Circuit Checking Protocols

In our implementation of the circuit checking method described in Section 2.1, we put significant effort into optimizing the runtime of the prover, achieving an implementation for which $\mathcal{P}$ takes time nearly linear in the size of the circuit. Nonetheless, this cost remains the chief limitation of the implementation.

We experimented with our implementation on circuits for three of our functions of interest: F_2 , F_0 and PMwW. We leave circuits for MVMULT to future work. Results are summarized in Table 1. Throughout, when we refer to $\mathcal{P}$ ’s runtime in an interactive protocol, we are referring to the total time *over all rounds* of the protocol. The speed per gate can be very high: $\mathcal{P}$ processed circuits with tens of millions of gates in a matter of minutes. For example, our basic implementation processed a circuit for F_0 with close to 16 million gates in under 9 minutes, or close to 30,000 gates per second. However, since the circuit’s size was more than 100 times larger than the universe over which the input is drawn, this translated to only about 300 items per second. The other costs incurred are very low. The verifier’s space usage and the communication cost are never more than a few dozen kilobytes, and the verifier processes close to thirty million updates per second across all stream lengths. The time for $\mathcal{V}$ to run the protocol is negligible compared to the (already low) time to compute the required low-degree extension of the input.

⁵Things are a little more complex in the case of circuit checking, as discussed in Section 3.2, but not dramatically so.

Figure 2: Experiments on non-interactive MVMULT protocols.

In Section 3.2, we discuss how adding additional gate types can reduce the cost of circuit checking. We demonstrate experimentally that adding gates which compute the 8th power ($\wedge 8$) or the 16th power ($\wedge 16$) of their inputs achieves substantial reductions in the size of the circuits needed. For F_0 , this reduced the number of rounds by nearly a factor of three, the prover time by close to 20%, and the overall communication cost by close to 30%. We also discuss in Section 3.2 how to (conceptually) replace a binary tree of addition gates with a single $\oplus$ gate of very large fan-in which sums all its inputs. For F_0 , this optimization further reduced both communication and number of rounds by 10-20%. The effect of $\oplus$ gates was much more pronounced for F_2 , where we saw an order of magnitude reduction in the number of rounds, and 5-fold reduction in communication cost. The change was larger here because the addition gates represent a much larger fraction of the gates in F_2 circuits than in F_0 circuits.

5.3 Specialized Protocols

We now describe our experiments with specialized protocols on a problem-by-problem basis. We find that specialized interactive protocols improve over the general-purpose construction by several orders of magnitude. Moreover, we demonstrate that the FFT techniques of Section 2 yield *non-interactive* protocols that easily scale to streams with billions of updates, improving over previous implementations by three orders of magnitude. The protocols are of various types: the basic multi-round protocols based on sum-check from [17] (MRS); multi-round protocols which use linearization from Section 4 (LIN); multi-round protocols based on circuit checking described in Section 3 (CC); the basic non-interactive protocols from [8] (NI); and the faster implementation of these protocols via FFT in Section 2 (NI-FFT).

Figure 3: Experimental results for F_0 .

F_2 : There are four known protocols for F_2 : one obtained via the general-purpose circuit-checking approach (CC), a specialized interactive protocol due to [17] (MRS), a naive implementation of the non-interactive protocol due to [8] (NI), and a non-interactive implementation based on our FFT techniques developed in Section 2 (NI-FFT). The results for CC are for our optimized implementation using $\oplus$ gates. Figures 1(b) and 1(c) illustrate the verifier's time and space costs for all four protocols, while Figure 1(a) illustrates the prover's runtime for these protocols. We used implementations of NI and MRS protocols for F_2 due to [17]. Note that in the case of NI and NI-FFT, the verifier behaves *identically*: the prover computes the same messages in both cases, but more quickly using FFT.

The main observation from Figures 1(b) and 1(c) is that the verifier's costs are extremely low for all four protocols. $\mathcal{V}$ processed over 20 million items/s across all stream lengths for all protocols. The space usage and communication cost for both interactive protocols (CC and MRS) is less than 1 kilobyte across all stream lengths tested, while the space usage for the non-interactive case is much larger but still reasonable (comfortably under a megabyte even for stream lengths in excess of 1 billion).

Figure 1(a) shows a clear separation between the four methods in $\mathcal{P}$'s effort in generating the proof. For large streams, it is clear that NI is not scalable, with $\mathcal{P}$'s runtime growing like $n^{3/2}$; this implementation failed to process streams larger than about 40 million updates. In contrast, the FFT-based implementation of the non-interactive protocol processed between 350,000 and 750,000 items per second for all tested values of n , even for values of n well into the billions. Thus, the FFT techniques of Section 2 speed up $\mathcal{P}$'s computation by several orders of magnitude compared to the naive implementation, and allowed the protocol to easily scale to streams with billions of items. As mentioned in Section 2, a wide variety of more complicated protocols use this protocols as a subroutine, and therefore these non-interactive techniques are as powerful as they are general.

For the multi-round protocols, circuit checking (CC) eventually outpaces NI, and scales linearly: the CC prover processed about 20,000 items per second across all stream lengths. Finally, the multi-round prover processed 20-21 million items per second. We conclude that special-purpose protocols should have substantial value, as our specialized non-interactive protocol was faster than Circuit Checking by more than an order of magnitude, and the specialized interactive protocol was faster by two orders of magnitude.

MVMULT: Figure 2 shows the behavior of our FFT-based implementation of the $(n^{1+\alpha}, n^{1-\alpha})$ non-interactive protocol for MVMULT described in Section 2. Recall that the parameter α allows us to tradeoff between communication and space used by the verifier. A convenient (and previously unremarked on) feature of this protocol is that when $\alpha = 0$, the honest prover's message consists simply of the vector $\mathbf{b}$. Consequently, we obtain an (n, n) protocol for which the prover can handle enormous throughputs: 30-50

α	Space	Comm	$\mathcal{P}$ time (s)	$\mathcal{V}$ time (s)
0	78.1 KB	78.1 KB	1.6	4.3
.15	19.9 KB	468.8 KB	33.9	3.0
.20	12.8 KB	937.5 KB	58.9	2.8
.25	7.8 KB	1.52 MB	61.5	2.6

Table 2: Non-interactive MVMULT results on matrices of size $10,000 \times 10,000$ (763 MBs of data).

million items/second as evidenced in Figure 2(b). In outsourcing settings where one can tolerate space usage $O(n)$ for the verifier, this protocol is truly ideal, as the prover need do nothing more than solve the problem, and the verifier’s computation consists only of maintaining n fingerprints. That is, this (n, n) protocol allows the user to obtain a strong security guarantee on the integrity of the query, almost for free. Note that for this problem, the size of the input is $O(n^2)$ for an $n \times n$ matrix, so $O(n)$ space at the verifier is still much smaller than the full input size.

The behavior becomes more interesting when we set $\alpha > 0$ —in this case, in addition to providing the correct answer, the prover has to do non-trivial computation to prove correctness. Because lower values of α mean less space but more communication (see Figure 2(c)), setting $\alpha > 0$ may be needed when the verifier is severely space-limited. It may also be necessary when the matrix is very wide: in full generality the protocol has communication and space cost $(mn^\alpha, n^{1-\alpha})$ for an $m \times n$ matrix. We show how different costs vary as a function of α : $\mathcal{V}$ ’s time to process the input (Figure 2(a)), $\mathcal{P}$ ’s time (Figure 2(b)), the communication cost (Figure 2(d)), and the space used by $\mathcal{V}$ (Figure 2(c)). Across all values of α , $\mathcal{P}$ can process in excess of 1 million items per second using our FFT techniques. The verifier runs over the stream slightly faster for higher values of α , because $\mathcal{V}$ maintains fewer fingerprints for larger α ’s. When $\alpha = 0$, $\mathcal{V}$ processed about 20 million items per second, and when $\alpha = .25$, $\mathcal{V}$ processed in excess of 30 million items per second. For concreteness, Table 2 displays the costs of the protocol when run on matrices of size $10,000 \times 10,000$.

F_0 : We implemented the $(\log u, \sqrt{n} \log u)$ interactive protocol of [17] described at the start of Section 4, which we refer to as the *bounded* protocol (B), since it uses a bound on F_∞ , the maximum frequency of any item. We compare this to the new *Linearization* based protocol (LIN) from Section 4.1, as well as to the circuit checking approach (CC) of Section 2.1. The circuit-checking results shown are from our optimized implementation using $\hat{8}$ gates.

Our focus is primarily on $\mathcal{P}$ ’s runtime, since we find that the bounded protocol is impractical for general streams: $\mathcal{P}$ ’s runtime is $\Theta(n^2)$. However, recall from Section 4 that $\mathcal{P}$ ’s run time in the bounded protocol can be made $O(F_\infty^2 n)$ when there is an *a priori* upper bound on F_∞ , or equivalently when $\mathcal{V}$ ’s memory is at least m/F_∞ for streams of length m . Figure 3(a) shows $\mathcal{P}$ ’s runtime for the bounded protocol as a function of the universe size n , for different bounds on F_∞ .

Figure 3(a) shows that for fixed F_∞ , the prover’s runtime in the bounded protocol grows linearly in n as expected. When F_∞ is very low, the protocol achieves reasonable throughputs, but as F_∞ grows the runtime rapidly becomes prohibitive. For example, $F_\infty = 30$ gives about 80,000 items per second, while $F_\infty = 200$ results in just 1,600 items/second. It is clear that this protocol will be unacceptably slow for realistic streams where F_∞ is in the thousands or larger.

In contrast, $\mathcal{P}$ ’s runtime in the linearization and circuit checking protocols is independent of F_∞ . For linearization, $\mathcal{P}$ ’s runtime grows slightly super-linearly in n (it is $\Theta(n \log^2 n)$ as shown in Section 4), and as a result the processing speed decreases slowly as the stream length increases (see Figure 3(b)). For short streams (e.g. $n = 2^{16}$), $\mathcal{P}$ handles about 17,000 items/second. For $n = 2^{24}$, $\mathcal{P}$ handles about 8,000 items

per second. Extrapolating the behavior to streams of length about 1 billion, $\mathcal{P}$ should handle about 4,500 items/second. These results are broadly consistent with its theoretical $\Theta(n \log^2 n)$ running-time bound, and represents a substantial improvement over the bounded protocol and the circuit checking protocol. In the circuit checking protocol $\mathcal{P}$ processes only 200-300 items per second across all stream lengths.

Note, however, that the overhead for the verifier in all three protocols is very light, making the costs compelling from $\mathcal{V}$'s perspective. In all protocols $\mathcal{V}$'s space was always well under 1KB; this cost was so low for all three protocols that we have omitted the corresponding plot. For the circuit checking and bounded protocols, $\mathcal{V}$ processed about 20 million updates per second, while for the linearization protocol, $\mathcal{V}$ processed 3-5 million items/second. The verifier in the bounded and circuit-checking protocols is faster than in the linearization protocol because, in the first two, $\mathcal{V}$ only requires evaluating a $\log n$ -variate polynomial at a random point, while the linearization protocol requires evaluating a $\log n + \log m$ -variate polynomial at a random point. The communication requirement grows larger for circuit checking and the bounded protocol, with the former approaching 100 KBs for universes of size 10 million, and the latter approaching similar amounts of communication when $F_\infty = 200$. In contrast, the communication under linearization was an order of magnitude lower, never more than a few KBs on all streams tested.

In summary, the bounded protocol may be preferable when F_∞ is at most a very small constant (less than about 30); otherwise, the linearization protocol dominates, with the only downside being decreased throughput of the verifier.

PMW: Our experiments on pattern matching showed broadly the same relative trends as for F_0 and are omitted for brevity.

5.4 Parallel Implementations

The prover's computations in all of the non-interactive protocols studied here are highly parallelizable, as noted previously. Indeed, using just three OpenMP⁶ statements, we were able to achieve more than a 7-fold speedup over the sequential implementation of the FFT protocol, by using all 8 cores of the multi-core machine our experiments were run on. Consequently, with 8 processors, the ratio between the speed of the MR and NI-FFT protocols for F_2 drops from 20-60 to 3-8. In theory, the interactive F_2 protocol is just as easy to parallelize as the non-interactive protocol; however, we did not find this to be the case in practice. The prover's computations in the multi-round protocol are so light-weight (as evidenced by its very high throughput) that memory access forms the principle bottleneck. In our test machine, all cores share a single pipe to memory, and the bottleneck remains. In other scenarios, such as each core having a separate pipeline to memory, multiple cores might yield more substantial speedups.

6 Conclusion and Future Directions

The ideas and techniques from interactive proof systems have transformed the landscape of computational complexity over the last two decades [3, 20]. Yet they have had relatively little practical impact thus far in the area of delegated computation. In this paper, we demonstrated that, when combined with significant engineering, interactive proof systems have sufficiently evolved to yield protocols suitable for everyday use.

A particularly encouraging feature of our experimental results is that $\mathcal{V}$'s runtime is dominated by the time required to evaluate the LDE of the input at a point r . For the low-complexity (linear or near linear time) computations we experimented on, this cost is actually comparable to the time required to solve the

⁶<http://www.openmp.org>

problem without a prover, assuming $\mathcal{V}$ had enough memory to store the input. But if we were to run our implementation on problems requiring superlinear time to solve, then $\mathcal{V}$ would save significant time as well as space (compared to solving the problem without a prover).

Moreover, if the cost of the LDE computation can be amortized over many queries, then $\mathcal{V}$ will save time as well as space even for very low-complexity functions. This is indeed possible for our non-interactive protocols, as there is *no* leakage of information from $\mathcal{V}$ to $\mathcal{P}$ as long as $\mathcal{P}$ does not learn whether $\mathcal{V}$ accepts or rejects after each query; soundness is therefore maintained even if $\mathcal{V}$ uses the same $\mathbf{r}$ in all instances of the protocol.

Such amortization for interactive protocols may also be possible in cases where $\mathcal{P}$ is not considered malicious, such as a user simply trying to detect a buggy algorithm. In this setting it is reasonable to use the same location $\mathbf{r}$ in all instances of the protocol even though soundness is not maintained theoretically. Thus, in these realistic situations, the amortized time cost to the verifier can be considerably sublinear in the input length, and our protocols will save the verifier both time and space.

The next step is to further advance the boundary of practicality. The chief obstacle for more general systems is the requirement of a circuit representation for computations, and the superlinear dependence of the prover's time on the size of the circuit. Various approaches offer themselves: either to design protocols which circumvent this circuit representation, or to improve the throughput by taking greater advantage of the inherent parallelism in the prover's work, e.g. via GPU implementation.

Acknowledgments

We thank Owen Arden, Varun Kanade, Guy Rothblum, Thomas Steinke, and Salil Vadhan for helpful discussions. We also thank Shafi Goldwasser, Yael Tauman Kalai, and Guy Rothblum for sharing the full version of [19].

A Details for Theorems 3.2-3.4

In this Appendix, we spell out the details of our efficient instantiation of the construction of [19]. Our results ensure that the prover can be implemented efficiently, and that the verifier can be implemented very efficiently for a large class of circuits.

A.1 Notation and Background

We adhere closely to the notation of [19]. We are given an arithmetic circuit C of gates with fan-in 2 over the field $\mathbb{F}$. C is in layered form and has size $S(n)$ and depth $d(n)$, where n is the number of input wires. For presentation purposes, assume that all layers of the circuit have at most n gates, and write $v = \log n$. For each $1 \leq i \leq d$, we associate the j 'th gate at layer i of C with the v -bit binary representation of j , and for $i > 1$, we define two functions, $add_i, mult_i : \{0, 1\}^{3v} \rightarrow \{0, 1\}$ which together constitute the wiring predicate of layer i of C . Specifically, these functions take as input three gate labels (j_1, j_2, j_3) , and return 1 if gate j_1 at layer $i - 1$ is the addition (respectively, multiplication) of gates j_2 and j_3 at layer i , and return 0 otherwise. We let $\tilde{add}_i, \tilde{mult}_i : \mathbb{F}^{3v} \rightarrow \mathbb{F}$ denote the *multilinear extensions* of add_i and $mult_i$ respectively. That is, $\tilde{add}_i$ and $\tilde{mult}_i$ are the unique multilinear polynomials over $\mathbb{F}$ that agree with add_i and $mult_i$ at all values in $\{0, 1\}^{3v}$.

We also define a function $V_i : \{0, 1\}^v \rightarrow \mathbb{F}$ to represent the values of the gates at layer i . That is, $V_i(j)$ equals the value of gate j at layer i . Let $\tilde{V}_i : \mathbb{F}^v \rightarrow \mathbb{F}$ denote the multilinear extension of V_i .

Recall from Section 2.1 that at iteration i of the protocol of [19], the sum-check protocol is applied to a certain $3v$ -variate polynomial f_i . We are ready to give the definition of f_i as promised. Given a vector $x \in \mathbb{F}^{3v}$, write $p = (x_1, \dots, x_v)$, $\omega_1 = (x_{v+1}, \dots, x_{2v})$ and $\omega_2 = (x_{2v+1}, \dots, x_{3v})$. Then we define

$$f_i(p, \omega_1, \omega_2) := \beta(p) \left(\tilde{add}_i(p, \omega_1, \omega_2) (\tilde{V}_i(\omega_1) + \tilde{V}_i(\omega_2)) + \tilde{mult}_i(p, \omega_1, \omega_2) \tilde{V}_i(\omega_1) \tilde{V}_i(\omega_2) \right). \quad (2)$$

Here, $\tilde{add}_i, \tilde{mult}_i$, and $\tilde{V}_i$ are as above, and $\beta(p)$ is a certain polynomial that depends only on p .

A.2 Making $\mathcal{P}$ Run in Time $O(S(n) \log S(n))$

In this subsection we show how to engineer an efficient prover. First we give an informal outline, then go on to make this more precise.

A.2.1 High-level Outline

In the j 'th round of the sum-check protocol applied to f_i , $\mathcal{P}$ is required to send the *univariate* polynomial

$$g_j(X_j) = \sum_{(x_{j+1}, \dots, x_{3v}) \in \{0, 1\}^{3v-j}} f_i(r_1^{(i)}, \dots, r_{j-1}^{(i)}, X_j, x_{j+1}, \dots, x_{3v}).$$

Theorems 3.2, 3.3, and 3.4 rely on the observation that, when $\tilde{add}_i$ and $\tilde{mult}_i$ are multilinear extensions, rather than arbitrary low-degree extensions, then each gate at layers i and $i - 1$ contributes to exactly one term in the sum.

More specifically, the key observation is that the multilinear extension of the wiring predicate acts as a sum of *variable-wise* indicator functions on boolean-valued variables, with one indicator function for each gate at the layer of interest. At any round j of the sum-check protocol, the “unbound” variables (i.e., those

appearing in the sum defining g_j) still only range over values in $\{0, 1\}$, and thus each gate $\mathbf{y}$ at the current layer of the circuit still contributes to only one term in the sum in intermediate rounds. Namely, $\mathbf{y}$ contributes to the unique term of the sum that agrees with the trailing bits in the binary representation of $\mathbf{y}$, despite the fact that “bound” variables may take values outside of $\{0, 1\}$.

A.2.2 Decomposing $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ as Sums of Variable-wise Indicator Functions

Since $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ are the multilinear extensions of the wiring predicate, we can write them explicitly as follows.

For $\mathbf{y} \in \{0, 1\}^{3v}$ let $\chi_{\mathbf{y}}(x_1, \dots, x_{3v}) = \prod_{k=1}^{3v} \chi_{y_k}(x_k)$, where $\chi_0(x_k) = 1 - x_k$ and $\chi_1(x_k) = x_k$. $\chi_{\mathbf{y}}$ is the unique multilinear polynomial that takes $\mathbf{y} \in \{0, 1\}^{3v}$ to 1 and all other values in $\{0, 1\}^{3v}$ to 0, i.e., it is the multilinear extension of the indicator function for boolean vector $\mathbf{y}$.

Notice that if $(x_{j+1}, \dots, x_{3v}) \in \{0, 1\}^{3v-j}$, then for any $(r_1, \dots, r_j) \in \mathbb{F}^j$,

$$\chi_{\mathbf{y}}(r_1, \dots, r_j, x_{j+1}, \dots, x_{3v}) = \begin{cases} \prod_{l=1}^j \chi_{y_l}(r_l), & \text{if } x_k = y_k \text{ for all } k \geq j+1. \\ 0, & \text{otherwise.} \end{cases} \quad (3)$$

Informally, Equation (3) implies that one may think of $\chi_{\mathbf{y}}$ acting as a *variable-wise* indicator function on boolean-valued variables.

Since $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ are multilinear extensions, they can be written as a sum of these $\chi_{\mathbf{y}}$ functions, where each gate $\mathbf{y}$ at layer $i-1$ contributes a term $\chi_{\mathbf{y}}$ to the sum. That is,

$$\tilde{\text{add}}_i(x_1, \dots, x_{3v}) = \sum_{\text{add gates } \mathbf{y} \text{ at layer } i-1} \chi_{\mathbf{y}}(x_1, \dots, x_{3v}) \quad (4)$$

and

$$\tilde{\text{mult}}_i(x_1, \dots, x_{3v}) = \sum_{\text{mult gates } \mathbf{y} \text{ at layer } i-1} \chi_{\mathbf{y}}(x_1, \dots, x_{3v}). \quad (5)$$

It is straightforward to observe the expressions on the right hand sides of Equations (4) and (5) are multilinear polynomials that agree with add_i and mult_i on boolean-valued inputs, and hence the right hand sides are equal to *the* multilinear extensions of add_i and mult_i respectively.

For any vector $\mathbf{x} = (x_{j+1}, \dots, x_{3v}) \in \{0, 1\}^{3v-j}$, and for any $(r_1, \dots, r_j) \in \mathbb{F}^j$, let $\mathbf{x}^*$ denote the vector

$$\mathbf{x}^* := (r_1, \dots, r_j, x_{j+1}, \dots, x_{3v}) \in \mathbb{F}^{3v},$$

and let $S_{\mathbf{x}}$ denote the set of gates at layer $i-1$ given by $\{\mathbf{y} \in \{0, 1\}^{3v} : y_k = x_k \text{ for all } k \geq j+1\}$. Equations 4 and 5 imply that

$$\tilde{\text{add}}_i(\mathbf{x}^*) = \sum_{\text{add gates } \mathbf{y} \in S_{\mathbf{x}}} \left(\prod_{l=1}^j \chi_{y_l}(r_l) \right), \quad (6)$$

and similarly

$$\tilde{\text{mult}}_i(\mathbf{x}^*) = \sum_{\text{mult gates } \mathbf{y} \in S_{\mathbf{x}}} \left(\prod_{l=1}^j \chi_{y_l}(r_l) \right) \quad (7)$$

A.2.3 Completing the Calculation

At round j of this sum-check protocol, the prover must compute the message

$$g_j(X_j) = \sum_{x_{j+1} \dots x_{3v} \in \{0,1\}^{3v-j}} f_i(r_1^{(i)}, \dots, r_{j-1}^{(i)}, X_j, x_{j+1} \dots x_{3v}).$$

Since g_j has degree three if we are using multilinear extensions, it suffices for the prover to send $g_j(r_j)$ for $r_j \in \{0, 1, 2\}$, as these evaluations uniquely define g_j .

Using Equations (6) and (7), we can now easily observe that each gate at layer $i - 1$ contributes to exactly one term in the sum. Specifically, for any term $\mathbf{x} = (x_{j+1} \dots x_{3v}) \in \{0, 1\}^{3v-j}$ in the sum, let $\mathbf{x}^*$ denote the vector

$$\mathbf{x}^* := (r_1^{(i)}, \dots, r_j^{(i)}, x_{j+1}, \dots, x_{3v}) \in \mathbb{F}^{3v}$$

as before, and let $p^* \in \mathbb{F}^v$ be the first v entries of this vector, $\omega_1^* \in \mathbb{F}^v$ the middle v entries, and $\omega_2^* \in \mathbb{F}^v$ the final v entries. Then combining Equations (6) and (7) with (2), we see

$$\begin{aligned} f_i(\mathbf{x}^*) &= \beta(p^*) \cdot \\ &\quad \left(\left(\sum_{\text{add gates } \mathbf{y} \in S_{\mathbf{x}}} \left(\prod_{l=1}^j \chi_{y_l}(r_l) \right) \right) \left(\tilde{V}_i(\omega_1^*) + \tilde{V}_i(\omega_2^*) \right) \right. \\ &\quad \left. + \left(\sum_{\text{mult gates } \mathbf{y} \in S_{\mathbf{x}}} \left(\prod_{l=1}^j \chi_{y_l}(r_l) \right) \right) \cdot \tilde{V}_i(\omega_1^*) \cdot \tilde{V}_i(\omega_2^*) \right). \end{aligned} \quad (8)$$

Each gate $\mathbf{y}$ at layer $i - 1$ is in $S_{\mathbf{x}}$ for exactly one $\mathbf{x} \in \{0, 1\}^{3v-j}$. Namely, $\mathbf{x}$ is the boolean vector equal to the last $3v - j$ bits of the binary representation of $\mathbf{y}$. Denote this vector by $\mathbf{x}(\mathbf{y})$, and similarly let $\mathbf{x}^*(\mathbf{y})$, $p^*(\mathbf{y})$, $\omega_1^*(\mathbf{y})$ and $\omega_2^*(\mathbf{y})$ denote the corresponding vectors implied by $\mathbf{x}(\mathbf{y})$.

Equation (8) implies that $\mathbf{y}$ contributes only to the term $\mathbf{x}(\mathbf{y})$ of the sum defining $g_j(r_j)$ for $r_j \in \{0, 1, 2\}$. That is, we may write

$$\begin{aligned} g_j(r_j) &= \sum_{\text{add gates } \mathbf{y} \text{ at layer } i-1} \beta(p^*(\mathbf{y})) \left(\prod_{l=1}^j \chi_{y_l}(r_l) \right) (\tilde{V}_i(\omega_1^*(\mathbf{y})) + \tilde{V}_i(\omega_2^*(\mathbf{y}))) \\ &\quad + \sum_{\text{mult gates } \mathbf{y} \text{ at layer } i-1} \beta(p^*(\mathbf{y})) \left(\prod_{l=1}^j \chi_{y_l}(r_l) \right) \cdot \tilde{V}_i(\omega_1^*(\mathbf{y})) \cdot \tilde{V}_i(\omega_2^*(\mathbf{y})). \end{aligned}$$

Thus, the prover can compute $g_j(0)$, $g_j(1)$, and $g_j(2)$ with a single pass over the gates at layer $i - 1$. By a similar calculation, all necessary $\tilde{V}_i(\omega_1)$ and $\tilde{V}_i(\omega_2)$ for each message of the prover can be computed with a single pass over the gates at layer i . In conclusion, as long as we use the multilinear extension of the circuit's wiring predicate, the prover can compute each message at layer i with a single pass over the gates at layer $i - 1$ and a single pass over the gates at layer i , performing a constant number of field operations for each gate. Thus, the prover runs in time $O(S(n) \log S(n))$ in total, where $S(n)$ is the size of the circuit.

A.3 Finishing the Proofs of Theorems 3.2 and 3.3

We have demonstrated that if the protocol of [19] is instantiated with the multilinear extensions of the circuits wiring predicate and gate value function, then $\mathcal{P}$ can be made to run in time $O(S(n) \log S(n))$. All that remains in proving Theorem 3.2 is to show that for any log-space uniform circuit, the verifier can evaluate $\tilde{\text{add}}_i(p, \omega_1, \omega_2)$ and $\tilde{\text{mult}}_i(p, \omega_1, \omega_2)$ in space $O(\log S(n))$. This holds because $\mathcal{V}$ can make an “implicit” pass over each layer of the circuit and compute the contribution of each gate to $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$. That is, $\mathcal{V}$ considers each gate y in turn, and computes y ’s contribution to $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ using Equations (4) and (5). This requires $O(S(n))$ time in total, but only $O(\log S(n))$ space, since $\mathcal{V}$ never needs to store an explicit representation of the circuit. Theorem 3.2 follows.

Theorem 3.3 follows from the additional observation that $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ do not depend on the input, nor do the random coins of the verifier, and these coins uniquely determine the points at which $\mathcal{V}$ must evaluate $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$. Thus, $\mathcal{V}$ can toss all her coins in the pre-processing phase and compute the necessary evaluations of $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$. $\mathcal{V}$ stores the answers and the random coins for use in the online phase. In the online phase, $\mathcal{V}$ only needs to spend $O(1)$ time per round of the protocol to check $\mathcal{P}$ ’s messages for consistency, and thus $\mathcal{V}$ takes time $O(d(n) \log S(n))$ in the online phase.

In streaming contexts, where $\mathcal{V}$ is more space-constrained than time-constrained, this may be acceptable. However, the solutions we adopt in our experimental implementation correspond to the stronger Theorem 3.4, which further reduces the space and time costs for the verifier.

A.4 Discussion and Formal Statement of Theorem 3.4

Now that we have defined the polynomial f_i to which the sum-check protocol is applied in the i ’th iteration of the construction of [19], we are ready to state Theorem 3.4 formally.

Theorem A.1 (Formal statement of Theorem 3.4.) *Let C be a log-space uniform circuit of size $S(n)$ and depth $d(n)$, and assume there exists an $O(\log(S(n)))$ -space, $\text{poly}(\log(S(n)))$ -time algorithm for evaluating $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ at a point, for all layers i of the circuit. Then $\mathcal{P}$ requires $O(S(n) \log S(n))$ time to implement the protocol of Theorem 3.1 over the entire execution. $\mathcal{V}$ requires space $O(\log S(n))$ and time $O(n \log n + d(n) \text{poly}(\log S(n)))$, where the $O(n \log n)$ term is due to the time required to evaluate the low-degree extension of the input at a point.*

The remainder of this section is devoted to discussing the applicability of Theorem A.1. We believe the assumption that the multilinear polynomials $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ can be evaluated quickly by a small-space algorithm is mild, in both theory and practice. We demonstrate this in three ways. First, we show that all four motivating problems in this work possess succinct circuits to which Theorem A.1 applies. Second, we identify a host of other important circuits from the algorithmic literature to which Theorem A.1 also applies. Third, we apply Theorem A.1 to a complicated circuit appearing in the proof of [19, Corollary 1], to obtain improved protocols for any language decidable by a (non-deterministic) Turing Machine in small space.

In essence, Theorem A.1 applies to any circuit with a “highly regular” wiring pattern; this explains why it applies to such a wide array of circuits. The details in the remainder of the section grow lengthy at times, but the thesis is clear: Theorem A.1 applies to most circuits that arise in both practical applications and theoretical constructions.

A.4.1 Wiring Predicates for F_2 , F_0 , PMWW, and MVMULT

We demonstrate that Theorem A.1 applies to all four circuits described in Section 3.

Figure 4: A circuit for F_2 on 4 inputs.

1. F_2 : Recall that the circuit for F_2 had a layer of multiplication gates used for computing the square of each input, and then subsequent levels formed a binary tree of addition gates used to sum up the results. A visual depiction of this circuit on $n = 4$ inputs is provided in Figure 4.

First, consider layer $d - 1$ immediately above the input gates, which consists of multiplication gates used to square each input; both the in-neighbors of gate i at layer $d - 1$ are equal to the i 'th input gate. Therefore, if $p = (p_1, \dots, p_v) \in \{0, 1\}^v$ denotes the boolean representation of a gate at layer $d - 1$, and $\omega_1 = (\omega_{1,1}, \dots, \omega_{1,v}) \in \{0, 1\}^v$ and $\omega_2 = (\omega_{2,1}, \dots, \omega_{2,v}) \in \{0, 1\}^v$ denote the boolean representation of two gates at the input layer, then mult_d evaluates to true if and only if $p = \omega_1 = \omega_2$, while add_d is identically zero. It is easily seen that the multilinear extension of mult_d is the polynomial

$$\tilde{\text{mult}}_d(p, \omega_1, \omega_2) = \prod_{j=1}^v (p_j \omega_{1,j} \omega_{2,j} + (1 - p_j)(1 - \omega_{1,j})(1 - \omega_{2,j})),$$

while the multilinear extension of add_d is the zero polynomial. Clearly, $\tilde{\text{mult}}_d$ can be evaluated at any point in $\mathbb{F}_p^{3v}$ in time and space $O(v) = O(\log n)$.

The rest of the circuit for F_2 consists of a binary tree of addition gates, which is used to sum up the squared item frequencies. Thus, $\tilde{\text{mult}}_i$ is the zero polynomial for all $i < d$. Meanwhile, for $i < d$ the predicate $\text{add}_i(p_1, \omega_1, \omega_2)$ evaluates to 1 if $\omega_1 = 2p$ and $\omega_2 = 2p + 1$, where here we are interpreting p , ω_1 , and ω_2 as integers. Thus, it can be seen that

$$\tilde{\text{add}}_i(p, \omega_1, \omega_2) = (1 - \omega_{1,1})\omega_{2,1} \cdot \prod_{j=2}^v (p_{j-1}\omega_{1,j}\omega_{2,j} + (1 - p_{j-1})(1 - \omega_{1,j})(1 - \omega_{2,j})).$$

Conceptually, the leading factor $(1 - \omega_{1,1})\omega_{2,1}$ ensures that ω_1 is even (i.e. its first bit is 0) and ω_2 is odd (i.e. its first bit is 1), while the expression

$$\prod_{j=2}^n (p_{j-1}\omega_{1,j}\omega_{2,j} + (1 - p_{j-1})(1 - \omega_{1,j})(1 - \omega_{2,j}))$$

ensures that the high-order $n - 1$ bits of ω_1 and ω_2 agree with the bits of p . $\tilde{\text{add}}_i$ is therefore the unique multilinear polynomial evaluating to 1 on boolean inputs (p, ω_1, ω_2) if $\omega_1 = 2p$ and $\omega_2 = 2p + 1$,

Figure 5: The first several layers of a circuit for F_0 on three inputs (in place of a fourth input is a “constant” gate with value one) over the field $\mathbb{F}_p$ with $p = 2^{61} - 1$. The first layer from the bottom computes a_i^2 for all i . The second layer from the bottom computes a_i^4 and a_i^2 for all i . The third layer computes a_i^8 and $a_i^6 = a_i^4 \times a_i^2$ for all i , while the fourth layer computes a_i^{16} and $a_i^{14} = a_i^8 \times a_i^6$ for all i . The remaining layers (not shown) have structure identical to the third and fourth layers until the value a_i^{p-1} is computed for all i , and the circuit culminates in a binary tree of addition gates.

and evaluating to 0 otherwise. Clearly $\tilde{\text{add}}_i$ can be evaluated at any point in time and space $O(v) = O(\log n)$. This completes the description of $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ for all layers of the circuit for F_2 .

2. F_0 : Recall that for each of the n inputs a_i , the circuit for F_0 from Section 3 computes a_i^{p-1} via $O(\log p)$ multiplications, and then sums the results via a binary tree of addition gates. We have already seen the wiring predicate for binary trees, so here we only sketch the wiring predicate for the a_i^{p-1} computation, omitting some details for brevity. We do so for the special case of $p = 2^{61} - 1$, which is the value of p used in our experiments, as this happens to have a particularly “regular” circuit for computing a^{p-1} ; the calculation would be similar but less symmetric for other values of p .

We may write $p - 1 = 2^{61} - 2$, whose binary representation is 60 1s followed by a 0. Thus, $a^{p-1} = \prod_{j=1}^{60} a^{2^j}$. The circuit computing a^{p-1} repeatedly squares a , and multiplies together the results “as it goes”. In more detail, for $i > 1$ there are two multiplication gates at each layer $d - i$ of the circuit for computing a^{p-1} ; the first computes a^{2^i} by squaring the corresponding gate at layer $i - 1$, and the second computes $\prod_{j=1}^{i-1} a^{2^{j-1}}$. See Figure 5 for a visual depiction of the first few layers of the F_0 circuit.

At a high level then, the wiring predicate $\text{mult}_i(p, \omega_1, \omega_2)$ tests equality of ω_1 and ω_2 with two strings that depend on the parity of p , as even values of p correspond to gates computing a^{2^i} while odd values correspond to gates computing $\prod_{j=1}^{i-1} a^{2^{j-1}}$. Thus, we may write

$$\tilde{\text{mult}}_i(p, \omega_1, \omega_2) = (1 - p_1) \chi_{\text{even}}(p, \omega_1, \omega_2) + p_1 \chi_{\text{odd}}(p, \omega_1, \omega_2),$$

where χ_{odd} and χ_{even} are multilinear extensions of the appropriate equality predicates, which do not depend on p_1 (we omit a precise definition of χ_{odd} and χ_{even} for brevity). This can clearly be evaluated in $O(v)$ time and space.

3. **PMwW**: The circuit for PMwW is similar to that for F_0 so we omit the details for this circuit.

4. **MVMULT**: The circuit described in Section 3 for MVMULT computes $(Ax - \mathbf{b})_i$ for all $1 \leq i \leq n$, and then applies the circuit for F_0 to the result. We have already sketched the wiring predicate for F_0 , so we need only describe the wiring predicate of the circuit C computing $(Ax - \mathbf{b})_i$ for all $1 \leq i \leq n$. For presentation purposes, we only describe the wiring predicate for a circuit C' which computes $(Ax)_i$ for all i . The wiring predicate for C' is simpler than that of C , since C requires some extra gates to “propagate” the entries of $\mathbf{b}$ up to the final layer of the circuit, where they are finally used to compute $(Ax - \mathbf{b})_i$ for all $1 \leq i \leq n$. We emphasize that Theorem A.1 applies to the circuit C as well.

Assume n is a power of 2. To simplify the wiring predicate of C' , we will treat C' as having $2n^2$ inputs, where the first n^2 inputs of C' are the entries of A in row-major order; and the last n inputs are the entries of the vector $\mathbf{x}$, with all the remaining inputs (between n^2 and $2n^2 - n$) set to 0 and ignored in subsequent layers. We emphasize that this convention does not increase the costs to either $\mathcal{P}$ or $\mathcal{V}$ in the protocol applied to C' .

Each of the $2n^2$ inputs can be specified with $1 + 2 \log n$ bits. Conceptually, the first bit indicates whether the input specifies an entry of A (a zero indicates yes). The next $\log n$ bits specify the row of A , and are zero for any entry of x . The last n bits specify the column of A or the entry of x . We therefore write an input to a gate as $h \circ i \circ j$, where $h \in \{0, 1\}$, $i, j \in \{0, 1\}^n$, and $\circ$ denote concatenation.

Layer $d - 1$ of C' computes $A_{ij}x_j$ for all $1 \leq i, j \leq n$; there are therefore n^2 gates at this layer, so each gate can be specified with $2 \log n$ bits. This layer consists only of multiplication gates, where the first input to gate $p = i \circ j$ has bit representation $0 \circ i \circ j$, while the second input has bit representation $1 \circ 0 \circ j$. Thus, for $p \in \{0, 1\}^{2 \log n}$, $\omega_1, \omega_2 \in \{0, 1\}^{2 \log n + 1}$,

$$\tilde{\text{add}}_d(p, \omega_1, \omega_2) = 0,$$

while

$$\begin{aligned} \tilde{\text{mult}}_d(p, \omega_1, \omega_2) &= (1 - \omega_{11}) \omega_{21} \cdot \\ &\left(\prod_{k=1}^{\log n} (p_k \omega_{1,k+1} + (1 - p_k) (1 - \omega_{1,k+1})) (1 - \omega_{2,k+1}) \right) \cdot \\ &\left(\prod_{j=\log n+1}^{2 \log n} (p_k \omega_{1,k+1} \omega_{2,k+1} + (1 - p_k) (1 - \omega_{1,k+1}) (1 - \omega_{2,k+1})) \right) \end{aligned}$$

Conceptually, the term $(1 - \omega_{11}) \omega_{21}$ ensures that the first bit of ω_1 is 0, and the first bit of ω_2 is 1. For $p = i \circ j$, the term

$$\prod_{k=1}^{\log n} (p_k \omega_{1,k+1} + (1 - p_k) (1 - \omega_{1,k+1})) (1 - \omega_{2,k+1})$$

ensures that the next $\log n$ bits of ω_1 equal i , while the corresponding bits of ω_2 are all 0. Finally, the term

$$\prod_{j=\log n+1}^{2 \log n} (p_k \omega_{1,k+1} \omega_{2,k+1} + (1 - p_k) (1 - \omega_{1,k+1}) (1 - \omega_{2,k+1}))$$

ensures that the last $\log n$ bits of both ω_1 and ω_2 equal j .

Subsequent layers of C' compute $\sum_{j=1}^n A_{ij}x_j$ for each $1 \leq i \leq n$, which is performed via a binary tree of addition gates for each i . We have already described the predicate for this wiring pattern in the paragraph on F_2 .

A.4.2 Other Circuits

Theorem A.1 applies to many other circuits that arise in the algorithms literature. Here we provide an incomplete list, sketching the necessary observations for each.

1. *Matrix Multiplication.* Theorem A.1 applies to the naive circuit of size $O(n^3)$ and depth $O(\log n)$ for multiplying two $n \times n$ matrices, which is similar to the circuit C' described in Section A.4.1 for MVMULT. More generally, other multiplication algorithms, such as Strassen's algorithm, are also amenable to encoding as circuits, reducing the size to $O(n^{2.807})$ in this case. We omit the details of these circuits for brevity.
2. *Rational permutations.* Rational permutations have arisen in the study of memory hierarchies [1, 10], and capture commonly-used operations such as matrix transposition and bit-reversal. Formally, a permutation Π on $[2^n]$ is rational if it can be expressed as a permutation π on bit positions i.e. $\Pi((x_1, \dots, x_n)) = (x_{\pi(1)}, \dots, x_{\pi(n)})$ [10]. There is a two-layer circuit C of size n for performing any rational permutation (i.e. producing output wires that are the permutation of the input wires). Let the 0'th input gate of C be a "constant gate" hard-coded to value zero. Each gate p at the non-input layer of C is an addition gate, whose first input is the constant gate, and whose second input is $\Pi(p)$. Then mult_1 is the zero polynomial, while

$$\tilde{\text{add}}_1(p, \omega_1, \omega_2) = \prod_{j=1}^{\log n} (1 - \omega_{1j}) (p_j \omega_{2, \pi(j)} + (1 - p_j)(1 - \omega_{2, \pi(j)})).$$

Conceptually, the $(1 - \omega_{1i})$ term ensures that $\omega_1 = 0$ while the term $(p_j \omega_{2, \pi(j)} + (1 - p_j)(1 - \omega_{2, \pi(j)}))$ ensures that $\omega_2 = \Pi(p)$. Clearly, $\tilde{\text{add}}_1$ can be evaluated at a point in $\text{polylog}(n)$ time as long as $\pi(i)$ can be evaluated in $\text{polylog}(n)$ time for $i \in \{0, 1\}^{\log \log n}$.

If a rational permutation is used as an intermediate step in a computation represented by a circuit C' , then we need not explicitly materialize the above "rational permutation" circuit C as an intermediate layer i of the larger circuit C' . Rather, we can simply modify the wiring predicate of layer i of C' to directly apply the rational permutation to its variables. That is, we replace $\text{add}_i(p, \omega_1, \omega_2)$ and $\text{mult}_i(p, \omega_1, \omega_2)$ with the polynomials $\tilde{\text{add}}_i(p, \Pi(\omega_1), \Pi(\omega_2))$ and $\tilde{\text{mult}}_i(p, \Pi(\omega_1), \Pi(\omega_2))$. It is easy to see that $\tilde{\text{add}}_i(p, \Pi(\omega_1), \Pi(\omega_2))$ and $\tilde{\text{mult}}_i(p, \Pi(\omega_1), \Pi(\omega_2))$ are multilinear polynomials as long as Π is a rational permutation, and these polynomials can be evaluated in $\text{polylog}(n)$ time as long as $\pi(i)$ can be evaluated in $\text{polylog}(n)$ time for $i \in \{0, 1\}^{\log \log n}$.

3. *Fourier Transform.* Theorem A.1 applies to an arithmetic circuit over the complex field $\mathbb{C}$ computing the standard radix-two decimation-in-time FFT (the most common form of the Cooley-Tukey algorithm [14]). Let $x \in \mathbb{C}^n$ be the input vector, where n is a power of 2, and let $X \in \mathbb{C}^n$ denote the output vector. The radix-two decimation-in-time FFT relies on the following recursion: Denoting the

even-indexed inputs x_{2k} by E_k and the odd-indexed inputs x_{2k+1} by O_k , it holds that

$$X_k = \begin{cases} E_k + e^{-2\pi ki/n} O_k & \text{if } k \leq n/2 \\ E_{k-n/2} + e^{-2\pi ki/n} O_{k-n/2} & \text{if } k > n/2 \end{cases}$$

The algorithm is sufficiently well-known that good introductions are readily available, along with illustrations of a circuit implementing the above recursion [36]. Essentially, the circuit performs a bit-reversal on its inputs (which can be implemented as a rational permutation described above), and then executes $\log n$ “stages”, where the k ’th output of stage i equals

$$V_i(k_1, \dots, k_n) = V_{i-1}(k_1, k_{i-1}, 0, k_i, \dots, k_n) + e^{-2\pi ki/n} V_{i-1}(k_1, \dots, k_{i-1}, 1, k_{i+1}, \dots, k_n). \quad (9)$$

Here $V_{i-1}(k)$ denotes the value of the k ’th output of the previous stage.

The i ’th stage can thus be implemented with two layers of gates; the first consists only of multiplication gates, and serves to multiply the outputs of the previous stage by the appropriate twiddle factors (the terms of the form $e^{-2\pi ki/n}$). The second layer consists only of addition gates, and combines outputs as in Equation (9). The wiring predicate of both layers essentially tests whether the k ’th bit of gate p is 0 or 1, and performs an appropriate equality test depending on the result. We have seen how to write equality tests of this form as succinct multilinear polynomials in the paragraph describing the circuit for F_0 in Section A.4.1.

A.4.3 More Efficient Protocols for Space-Bounded Computation

Our final result of this section is to obtain more efficient protocols for any language decided by a non-deterministic Turing Machine in small space. In the full version of [19], Goldwasser, Kalai, and Rothblum obtain the following result.

Lemma A.2 ([19], full version) *Let $\mathcal{L}$ be any language solvable by a non-deterministic Turing Machine T in space $s(n) = \Omega(\log n)$ and time $t(n)$. Then there is an arithmetic circuit C over an extension field of $\mathbb{F}_2$ computing L , where C has size $S(n) = \text{poly}(2^{s(n)})$, and depth $d(n) = O(s(n) \log t(n))$. Moreover, for $1 \leq i \leq d(n)$, there exist polynomial extensions $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ of the functions add_i and mult_i , where $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ have degree $\text{poly}(s(n))$ and can be evaluated at a point using space $O(\log S(n))$ and time $\text{poly}(s(n))$.*

We show that in fact the circuit C satisfies the following stronger property:

Corollary A.3 *Let C , add_i and mult_i be as in Lemma A.2. For $1 \leq i < d(n)$, the multilinear extensions $\tilde{\text{add}}_i$ and $\tilde{\text{mult}}_i$ of the functions add_i and mult_i , can be evaluated at a point using $O(\log S(n))$ words of memory and time $\text{poly}(s(n))$, while $\tilde{\text{add}}_{d(n)}$ and $\tilde{\text{mult}}_{d(n)}$ can be evaluated at a point using $O(\log S(n))$ words of memory and time $O(n \cdot s(n) \log n)$.*

Thus, Theorem A.1 implies that in applying the protocol of [19] to C , the prover can be made to run in time $O(S(n) \log S(n))$, rather than $\text{poly}(S(n))$, with a verifier who uses $O(\log S(n))$ space and runs in time $O(n \cdot s(n) \log n + d(n) \text{polylog}(S(n)))$, where $S(n)$ is the size of C . Notice in particular that for any language in $\mathcal{NL}$, the verifier runs in time $O(n \log^2 n)$.

In essence, there are two sources of overhead in the protocol implied by Lemma A.2, where by overhead we mean the extra computation $\mathcal{P}$ must do to solve the problem *verifiably*, rather than just solving the

problem in an unverifiable manner. First, there is overhead in representing a uniform computation as a (potentially large) circuit C rather than as a non-deterministic Turing Machine T . Second, there is additional overhead caused by the fact that in Lemma A.2, the prover takes time superlinear in the size of C . Our results in this section remove the latter source of overhead, or at least reduce it to a logarithmic factor rather than polynomial factor, while maintaining a super-efficient verifier.

Description of C . In order to present our result, we must first summarize the circuit C as defined in [19], which can be described as follows. The non-deterministic Turing Machine T is assumed without loss of generality to have a unique accepting configuration. The circuit C consists of two stages: the first stage computes the adjacency matrix of the configuration graph of T on input x , which requires just a single layer of gates, while the second stage determines whether there is a path from the starting configuration of T on input x to the accepting configuration. The second stage determines whether such a path exists by a process resembling repeated squaring of the adjacency matrix of T .

More specifically, closely following the notation in the full version of [19], a configuration of T can be specified as a tuple $u = (q, i, j, t) \in \{0, 1\}^{g(n)}$, where $g(n) = O(1) + \log n + \log s(n) + s(n) = O(s(n))$. In this tuple, q is a boolean vector describing the machine's state ($O(1)$ bits), i is the boolean representation of the location of the input-tape head ($\log n$ bits), j is the location of the work-tape head ($\log s(n)$ bits), and t represents the contents of the work tape ($s(n)$ bits). The configuration graph G of T is a directed acyclic graph with $2^{g(n)}$ nodes, one for each configuration of T , and an edge from u to v if T can move in one step from configuration u to configuration v . We include self-loops in this graph.

As in the full version of [19], let B_x denote the adjacency matrix of T . The circuit C first computes the entries of B_x , and then computes $\log t(n)$ matrices $B_{\log t(n)}, \dots, B_0$, where the (u, v) 'th entry of B_p is 1 if there is a path of length at most $2^{\log t(n) - p}$ from u to v in G . The matrix B_p is obtained from B_{p+1} by a process resembling repeated squaring of B_x using naive matrix multiplication.⁷ The wiring structure of this stage of the circuit is similar to that for naive matrix-vector multiplication, and it is straightforward to observe that the multilinear extensions of add_i and mult_i for these layers can be evaluated in $O(\log S(n))$ time and using $O(\log S(n))$ words of space. We omit these details for brevity.

Multilinear Extension of the Remaining Layer. Thus, we need only show that the multilinear extensions of the wiring predicate of the layer of C computing the entries of B_x can be evaluated using $O(\log S(n))$ words of memory and $O(n \cdot s(n) \log n)$ time. Assume that C has a designated input gate whose value is set to 0, and another whose value is set to 1; we call these the constant-0 and constant-1 input gates, respectively. In determining the value of $B_x[u, v]$, the full version of [19] demonstrates that there are 4 cases to consider. Notice configuration u only reads one input bit, bit x_i .

1. Configuration u can always go to v , regardless of x_i . Then $B_x[u, v] = 1$.
2. Configuration u can never go to v , regardless of x_i . Then $B_x[u, v] = 0$.
3. Configuration u can go to v only if $x_i = 1$. Then $B_x[u, v] = x_i$.
4. Configuration u can go to v only if $x_i = 0$. Then $B_x[u, v] = 1 + x_i$, with arithmetic done over an extension field of $\mathbb{F}_2$.

Thus, all gates are layer $d(n) - 1$ of C are addition gates. In Case 1 above, the first input to gate (u, v) is the constant-0 input gate, while the second is the constant-1 input gate. In Case 2, both inputs to gate (u, v)

⁷More specifically, $B_p[u, v] = 1 + \prod_{w \in \{0, 1\}^{g(n)}} (1 + B_p[u, w]B_p[w, v])$, where all arithmetic is done over an extension field of $\mathbb{F}_2$.

at layer $d(n) - 1$ equal the constant-0 input gate. In Case 3, the first input to gate (u, v) is the constant-0 input gate, and the second input to gate (u, v) is the i 'th input gate. In Case 4, the first input to gate (u, v) is the constant-1 input gate, and the second input to gate (u, v) is the i 'th input gate.

Write $u = (q_1, i_1, j_1, t_1)$ and $v = (q_2, i_2, j_2, t_2)$. The fact that the multilinear extension $\tilde{\text{add}}_{d(n)}(p, \omega_1, \omega_2)$ can be evaluated using $O(\log S(n))$ words of memory and time $O(n \cdot s(n) \log n)$ relies on the fact that *computation is local*. More specifically, determining which of the four cases (u, v) is in depends only on the states q_1 and q_2 (of which there are only $O(1)$ possibilities), the value of the j_1 th bit in both t_1 and t_2 (of which there are only 4 possibilities), determining whether the work-tape head can move $j_2 - j_1$ locations to the right (this requires $j_2 - j_1 \in \{-1, 0, 1\}$, and hence there are only $O(s(n))$ valid possibilities for j_2 and j_1), determining whether the input-tape head can move $i_2 - i_1$ locations to the right (this requires $i_2 - i_1 \in \{-1, 0, 1\}$, and hence there are only $O(n)$ valid possibilities for i_2 and i_1), and determining whether all other entries of t_1 and t_2 are identical (the multilinear extension of this predicate is succinct).

For example, p is in Case 1 iff

1. All bits of t_1 and t_2 other than bit j_1 are equal, and
2. Given state q_1 and the value read by the work-tape head t_{1,j_1} , it holds that no matter the value of x_i , the non-deterministic machine can move to state q_2 , move its output-tape head $j_2 - j_1$ positions to the right, set bit j_1 of its work tape equal to t_{2,j_1} , and move its input head move $i_2 - i_1$ positions to the right.

Let S be the set of all values $(q_1, q_2, i_1, i_2, j_1, j_2, t_{1,j_1}, t_{2,j_1}) \in \{0, 1\}^{O(s(n))}$ values satisfying Property Two above. Notice all elements of S can be enumerated in time $O(n \cdot s(n))$.

For $p = (q_1, i_1, j_1, t_1, q_2, i_2, j_2, t_2) \in \{0, 1\}^{2g(n)}$, $\omega_1, \omega_2 \in \{0, 1\}^{\log n}$, consider the multilinear polynomial

$$\chi_{\text{Case 1}}(p, \omega_1, \omega_2) = \left(\sum_{x \in S} \chi_x(p_S) \right) \chi_{\bar{S}}(p_{\bar{S}}) \chi_0(\omega_1) \chi_1(\omega_2),$$

where p_S denotes the vector p restricted the entries corresponding to elements in S , χ_x is the multilinear polynomial testing for equality with x , $\chi_{\bar{S}}$ is the multilinear polynomial for testing that all bits of t_1 and t_2 other than i_1 are equal, χ_0 is the multilinear polynomial for testing that ω_1 is equal to the index of the constant-0 gate, and χ_1 is the multilinear polynomial for testing that ω_2 is equal to the index of the constant-1 gate. This polynomial can clearly be evaluated in in time $O(n \cdot s(n) \log n)$ using $O(\log S(n))$ words of memory, and it evaluates to 1 on boolean input (p, ω_1, ω_2) to 1 if p is in Case 1 and ω_1 and ω_2 are as required by Case 1, and evaluates to zero otherwise.

Similar polynomials $\chi_{\text{Case 2}}$, $\chi_{\text{Case 3}}$, $\chi_{\text{Case 4}}$ can be constructed for Cases 2-4. Thus, we can write

$$\tilde{\text{add}}_i(p, \omega_1, \omega_2) = \sum_{j=1}^4 \chi_{\text{Case } j}(p, \omega_1, \omega_2),$$

which can clearly be evaluated in time $O(n \cdot s(n) \log n)$ and space $O(\log S(n))$.
